Abstract

This paper presents a toolkit to solve for equilibrium in a computationally efficient way in economies facing the effective lower bound on the nominal interest rate under a special assumption about the underlying shock process, a two-state Markov process with an absorbing state. We illustrate the algorithm in the canonical New Keynesian model by replicating the optimal monetary policy in [Eggertsson and Woodford \(2003\)](#), and we show how the toolkit can be used to analyse the medium-scale dynamic stochastic general equilibrium model developed by the Federal Reserve Bank of New York. As an application, we show how various policy rules perform relative to the optimal commitment equilibrium. A key conclusion is that previously suggested strategies – such as price level targeting and nominal GDP targeting – do not perform well when there is a small drop in the price level, as observed during the Great Recession, because they do not imply a sufficiently strong commitment to low future interest rates (“make-up strategy”). We propose two new policy rules – the *cumulative nominal GDP targeting rule* and the *symmetric dual-objective targeting rule* – that are more robust. Had these policies been in place in 2008, they would have reduced the output contraction by approximately 80 percent. If the Federal Reserve had followed average inflation targeting – which arguably approximates the policy framework announced in August 2020 – the output contraction would have been roughly 25 percent smaller.

Keywords: occasionally binding constraints; effective lower bound; regime shifts; first-order perturbation; simple policy rules; nominal GDP target;

JEL Classification: E31, E40, E50, E60

*This paper was prepared for the Alejandro Justiniano Memorial Conference at the Federal Reserve Bank of Chicago.

1 Introduction

The effective lower bound (ELB) on nominal interest rates has been widely studied in recent years. The standard way to analyse this problem is with dynamic stochastic general equilibrium (DSGE) models, in which the ELB is an inequality constraint on the nominal interest rate. However, inequality constraints complicate the application of standard solution strategies – for example perturbation methods. These methods approximate the behaviour of a dynamic nonlinear model around a point (usually via linearisation) using differentiability assumptions. Occasionally binding constraints pose a challenge for direct application of these methods.

In this paper, we present a toolkit aiming to facilitate the application of a generalised version of the solution method first used by Eggertsson and Woodford (2003), who analyse the ELB in the context of a two-state Markov process for the exogenous shocks with an absorbing state.¹ We illustrate the algorithm in the canonical New Keynesian (NK) model and in the medium-scale DSGE model developed by the Federal Reserve Bank of New York (FRBNY). As an application, we consider various policy rules and study their performance relative to the optimal commitment equilibrium. Previously suggested policy rules – such as price level targeting and nominal GDP targeting – do not perform well when the price level does not fall by a large amount, as observed during the Great Recession, because they do not entail sufficiently strong commitment to a low future interest rate (that is, an adequate make-up strategy). This also applies to a policy rule we term *average inflation targeting*, which arguably approximates the policy regime of the Federal Reserve as presented by Powell (2020). To address this shortcoming, we propose two new policy rules – what we call *cumulative nominal GDP targeting* and *symmetric dual-objective targeting rule* – that are more robust. Had either of these policies been in place in 2008 and believed to be credible, our model simulation suggests the Federal Reserve would have reduced the output contraction (relative to trend) by about 80-90 percent. The comparable number for the average inflation targeting rule is 25 percent (Table 3).

Several strategies have been proposed to deal with inequality constraints in DSGE models. Eggertsson and Woodford (2003) exploit a particular structure for exogenous disturbances: the posited shock process implies that the economy unexpectedly moves to a crisis state and then reverts back to the steady state with a fixed probability. Once back to the steady state, it stays there forever (that is, the steady state is an absorbing state). The idea behind the approach is intuitive: instead of treating a single dynamical system that contains both a set of equality constraints and a set of occasionally binding inequality constraints, we split the system into several parts we call *regimes*, each of which contains equality constraints exclusively. Once the system is cast in this form, we can apply perturbation methods since each equation is differentiable.

An application to the ELB scenario should make the point clear. We distinguish among four regimes, each of them corresponding to a different combination of the status of the inequality constraint (for example, ELB binding or not) and the exogenous Markov disturbance (crisis or steady state). For the regimes in which the ELB is not binding, we treat the model as if the ELB was not present. In the other two regimes, when the ELB constraint is binding, the equilibrium conditions are characterised by an *equality* constraint (for example, $i_t = i_{t-1} = 0$). Since all four dynamical systems are described by a set of equations, each can be solved using perturbation techniques.

The assumptions about the shock structure allow us to solve the model recursively in regimes. Starting from the last regime, in which the ELB is not relevant, we work backwards to the period when the shock

¹Source codes, guides and examples are maintained at <https://github.com/gautieggertsson/2-state-toolkit>.

hits the system and we obtain a piecewise solution. Since outcomes in later regimes influence behaviour in earlier ones through expectations, the strategy is not based on a simple merger of separate models.

Our approach has two key advantages: first, its relative simplicity allows us to handle models with many state variables; second, unlike local-solution techniques, our strategy allows us to assume the basic stochastic structure, making it attractive for simple estimations.² Note that it is not just the interest-rate constraint, but any model with a constraint that is temporarily binding can be solved using our toolkit.

As a new feature, the toolkit uses an algorithm that generalises the solution method in [Eggertsson and Woodford \(2003\)](#). In particular, it allows for the case of a regime in which the two-state Markov process is in the crisis state but the ELB is not binding. This feature is of particular importance when we analyse policy rules, as a common property of policy rules is that they imply an inertial response of the interest rate. An example is a Taylor-type rule with lagged terms for the nominal interest rates. Rules of this kind often do not imply an immediate reduction of the interest rate to the ELB once the two-state Markov disturbance switches to the crisis state. The new feature is thus a meaningful addition and facilitates the analysis of different types of policy rules in the presence of an ELB, which is the main application in this paper.

The idea of attacking the problem by constructing a piecewise solution is not new, nor is the idea of a toolkit for applying the solution. In fact, [Guerrieri and Iacoviello \(2015\)](#), henceforth *OccBin*, provide a toolkit for solving dynamic models with occasionally binding constraints in a similar fashion. The main difference is that we do not assume perfect foresight – that is a deterministic setting. This feature also differentiates our approach from several other strategies, such as the *extended path* (EP) algorithm. To achieve this, we rely on the specific shock structure implied by a two-state Markov process with an absorbing state. Expectations about the future path of variables are a crucial component of models related to the ELB (for example, uncertainty about whether the economy will hit the ELB and uncertain timing of lift-off), and hence allowing for uncertainty is a useful feature of the toolkit.

Adding a two-state Markov process with an absorbing state usually implies the following timing for the models analysed with the toolkit: initially, a shock hits the economy and the response of the central bank might be to immediately lower the interest rate to zero. In every period the disturbance reverts to its initial absorbing condition with some probability. There is often a transition period, lasting from the point when the shock reverts to its initial level until all other variables of the model return to their steady-state values. One benefit of our setup is that one can separately calibrate the expected time during which the constraint is binding from the actual realised time. Empirical evidence on the Great Recession, for instance the *Blue Chip* financial forecasts ([Aspen Publishers 2008-12](#)), suggests that market participants were expecting the ELB to be binding for a much shorter time than turned out to be the case. We account for this evidence, and we analyse several questions related to it, such as what the output gains would have been had the Federal Reserve adopted alternative policy regimes to that in place during the financial crisis of 2008.

The expected duration of the ELB episode is not necessarily exogenously determined simply by the transition probability of the shock; in the case of a central bank that has commitment power, the duration of the binding ELB will typically be *longer* than the persistence of the disturbance in its crisis state. The periods in which the inequality constraint is binding therefore do *not coincide* with the periods in which the shock is in the low state. This means that the duration at the ELB is endogenously determined in

²[Denes, Eggertsson and Gilbukh \(2013\)](#) contains a simple estimation that exploits the two-state Markov chain that the toolkit solves for.

the model, as it depends on the optimal decisions taken by the monetary authority, which are a function of, among other things, the realisation of the shock. This is a key challenge in solving the model and is discussed in detail in the paper.

Our main application is monetary policy when the interest rate reaches the ELB. Since the standard policy tool of affecting nominal interest rates is not available at that point, influencing expectations about their future path becomes the main lever through which the monetary authority can affect *present* variables. In this environment, policy rules that are able to mimic some form of commitment from the central bank are believed to perform relatively well. For example, [Eggertsson and Woodford \(2003\)](#), who predict strong deflation, argue that rules that commit to bringing the price level back to pre-crisis levels and to inflate in the future are very effective. A key finding is that price level targeting and nominal GDP targeting do not do well if there is little fall in inflation, as was the case during the financial crisis of 2008 in the United States. The policy of price level targeting we consider is arguably equivalent to the policy of average inflation targeting recently adopted by the Federal Reserve when it amended its policy framework in August 2020, if the average is taken over a sufficiently long period. We also consider an average inflation targeting regime for which the average time period is shorter. This policy provides even less stimulus at the ELB.

In addition, we discuss our two proposed rules – the *cumulative nominal GDP targeting rule* and the *symmetric dual-objective targeting rule* – that imply a commitment from the central bank to make up for past deviations from the target price level and output. We study the two rules’ performance in the standard NK model and in the NYFRB DSGE model and show that they generally perform better than the standard rules in the literature. We show this in an environment with low inflation and small movement in the price level, as experienced during the Great Recession. Since both rules imply an aggressive reaction to past output misses, they communicate that the longer the crisis is, the more accommodative monetary policy will be. This in turn generates enough stimulus to prevent a large recession in the first place.

Among previously proposed policy rules, the ones that perform best are the superinertial rule described in [Rotemberg and Woodford \(1999\)](#) and the augmented Taylor rule detailed by [Reifschneider and Williams \(2000\)](#). Policy rules that do not perform as well include price level targeting, nominal GDP targeting and average inflation targeting, a result in line with [Reifschneider and Wilcox \(2019\)](#). The key problem with these rules is that they do not prescribe strong-enough stimulus when inflation is not falling.

The most important advantage of the stochastic structure our toolkit embodies is that it allows for a clear distinction between the expected duration of the shock and the realised duration of it, though the two of course coincide under perfect foresight. This allows us to clearly show the advantage of policy commitments, such as those exemplified by our targeting rules, relative to optimal time-dependent policy – a strategy that resembles the interventions of several central banks during the crisis of 2008. Under optimal time-dependence, the duration of the ELB is tied to calendar time. In contrast, the targeting rule we consider implies a duration at the ELB that depends upon economic conditions. We highlight that a properly chosen state-contingent policy rule vastly outperforms optimal time-dependent policy, a distinction that is not as transparent in a deterministic setting.

In an additional application, we utilise our toolkit to contribute to a recent debate on the economic effects of forward guidance policy. We distinguish two cases: in the standard theory, forward guidance creates additional stimulus by a fully credible announcement that the central bank will keep the interest rate at the ELB for additional periods; this is an expansionary policy. The second case is what [Campbell et al. \(2012\)](#) call *Delphic* forward guidance and [Nakamura and Steinsson \(2018\)](#) refer to as *information*

effects. Here, the expected duration of the ELB episode lengthens as well, but this time solely because the revelation of information leads agents to update their beliefs about economic fundamentals, which entails a contraction. We show that both scenarios can match the same increase in the expected duration at the ELB but that they lead to vastly different outcomes.

The paper is structured as follows: section 2 outlines how the solution method relates to the literature; section 3 presents the solution algorithm; section 4 provides a few applications in the context previously defined; section 5 applies our toolkit to the medium-scale FRBNY DSGE model; section 6 concludes.

2 Related Literature

There exists a sizeable literature on solution methods for DSGE models.³ Solution strategies can be classified into local and global. The former include perturbation methods, while the latter includes projection methods. Projection methods can handle occasionally binding constraints in a direct way, but they are associated with a considerable computational burden and suffer from the curse of dimensionality.

Our approach relies on perturbation. Generally, provided a system is well behaved, perturbation methods can handle large models with many state variables and provide a high quality of approximation. However, in the presence of occasionally binding constraints differentiability does not hold everywhere.

Several attempts have been made to address this issue: our approach is a reworking and extension of the algorithm proposed in Eggertsson and Woodford (2003) that solves an NK model with a ELB in a fully stochastic setting. Jung, Teranishi and Watanabe (2005) presents another early strategy based on a piecewise solution, but in a deterministic environment. The paper closest in spirit to ours is Guerrieri and Iacoviello (2015). Its toolkit, *Occbin*, solves deterministic dynamic models with occasionally binding constraints by piecewise first-order perturbation. It can handle an AR(1) shock structure, independent shocks, and several alternations between slack and binding modes in one simulation. However, it assumes perfect foresight. From this discussion it should be clear that our toolkit is complementary to *OccBin*. Each is tailored to a particular set of questions, and both are easily implementable.

Doubts have been raised about whether linearisation offers a good approximation to the fully nonlinear system dynamics in the presence of the ELB (see, for example, Boneva, Braun and Waki 2016). Eggertsson and Singh (2019) look at the nonlinear version of Eggertsson and Woodford (2003) and find that the approximation error is modest even for large disturbances, provided the approximated solution is parameterised to match the same empirical evidence and the nonlinear solution. They also comment on poor approximation results in relation to Rotemberg pricing,⁴ a finding they ultimately trace to how the cost of price changes appears in the resource constraint of the model, rather than to errors introduced by linearisation.

One way to account for the ELB is to replace the inequality constraint with news shocks that are realised some time before they enter the model's equations. Laséen and Svensson (2011) and Holden and Paetz (2012) develop this point: they use such disturbances to transform a nonlinear constraint into as-if linear models. Their approaches are able to handle higher-order approximations and uncertainty. Holden (2016) offers a *Dynare* toolbox for easy implementation of the procedure, *DynareOCB*, which provides reliable accuracy with sufficient speed.

Another local method of solving large systems in reasonable time is the EP algorithm, proposed by Fair

³For an overview, we refer to the recent handbook chapter by Fernández-Villaverde, Rubio-Ramírez and Schorfheide (2016).

⁴This point was also made in Miao and Ngo (2019).

and Taylor (1983) and applied to a model with an ELB by Adjemian and Juillard (2011). This method sets a terminal date when the solution trajectory is assumed to be sufficiently close to the steady state. The EP algorithm is solved under the assumption of perfect foresight: at each point in time, all future shocks are assumed to be equal to their expected values of zero. Adjemian and Juillard (2013) note that ignoring Jensen's inequality under an EP approach leads to a sizeable approximation error in models with occasionally binding constraints. The authors extend the EP to a stochastic extended path algorithm which is more suitable for a setting with nonlinear constraints. It is a middle ground between perfect foresight and a fully stochastic setting: for some finite number of periods ahead, the setting is stochastic (for example, the expectation is explicitly approximated via quadrature integration) while after that period all disturbances are assumed to be zero.

Another strategy is to replace the inequality constraint by a smooth penalty function, thereby eliminating the inequality constraints from the model (this is also referred to as the barrier method). The idea is to penalise the agents' utility in cases in which the inequality constraint is violated. This method is outlined in Judd (1998) and put to use in Preston and Roca (2007) and Kim, Kollmann and Kim (2010), among others. In the context of the ELB, it was first applied in Rotemberg and Woodford (1997).⁵

The advantage of the approaches discussed so far is that they can manage medium- to large-sized models in reasonable time. Global solution methods can account for nonlinearities and deliver solutions with high precision, but they suffer from the curse of dimensionality. However, improvements in computation power and methods make this more direct approach increasingly attractive and applicable.⁶

Some papers using projection methods to analyse the ELB should also be mentioned here: Adam and Billi (2006) and Nakov (2008) work with the linearised system of equations of standard NK models, and the ELB is the only source of nonlinearity. Fernández-Villaverde, Rubio-Ramírez and Schorfheide (2016) solve the fully nonlinear model and highlight the benefits of this approach.

It is worth highlighting an important limitation of the solution method applied in this paper that makes it less appropriate for analysing some questions. Because the shock that generates the ELB returns to an absorbing steady state, our method is not suitable to address questions related to repeated episodes of the ELB. For example, if one wants to address how anticipation of future ELB episodes matter for policy under normal circumstances, the method developed here is not useful, absent further extensions. Global methods, in contrast, are well suited for this class of questions.

Given the numerous and powerful alternatives available, we do not claim superiority to any of the presented methods. Which approach is best suited for a particular problem will have to be evaluated on an individual basis. Our method has the advantage of tractability, simplicity, fast implementation, and the flexibility to account for a particular kind of uncertainty that has been widely discussed in the literature.

⁵An application to the ELB is also discussed in Woodford (2003), chapter 6, section 4.2.

⁶Maliar and Maliar (2015) is a recent attempt to ameliorate the curse of dimensionality when using projection methods. The key to its result is to repeatedly choose the grid on which the projection method operates in a smart way, using a stochastic-simulations approach. Gust et al. (2017) use this method to solve a medium-scale DSGE model with an occasionally binding zero-lower-bound constraint and use the methodology to estimate the model using Bayesian methods.

3 A Piecewise Linear Solution to Rational Expectations Models with Inequality Constraints

3.1 Basic Idea

In this section we outline our approach of applying perturbation methods to models with inequality constraints.⁷ Technically, the use of the implicit function theorem (IFT), on which perturbation methods rely, requires that the function approximated be smooth. Inequality constraints introduce a kink in the model at the point at which the inequality constraint becomes binding. On a more intuitive level, once the inequality constraint becomes binding (or slack, depending on the point being approximated), local approximation via IFT becomes inaccurate.

The basic idea of our approach is to circumvent this problem: we split the model into several parts, called *regimes*, depending on which set of equations applies. This strategy decomposes the inequality constraints that characterise the model in general into several equality constraints that characterise each regime separately. This turns one system with occasionally binding constraints into several interlinked systems. Critically though, it does not amount to simply transforming the problem into independent dynamical linear systems; rather, optimal decision making in the current regime takes into account uncertainty as to what regime will govern future dynamics of the model, thus linking the dynamics of one regime to the next.

We assume the fundamental disturbance $\epsilon_t \in \{\epsilon_L, \epsilon_H\}$ hitting the system to be characterised by a two-state Markov process with an absorbing state. That is, $P(\epsilon_{t+1} = \epsilon_L | \epsilon_t = \epsilon_L) = \mu$ and $P(\epsilon_{t+1} = \epsilon_H | \epsilon_t = \epsilon_H) = 1$.⁸ This assumption buys us a lot, as the shock structure allows us to decompose a single dynamical system into several regimes.⁹ In the applications we consider in this paper, the regimes are the following:

0. $0 < t < \tilde{T}$: the shock is in the low state ($\epsilon_t = \epsilon_L$) and the ELB is not yet binding;¹⁰
1. $\tilde{T} \leq t < \tau$: the shock is in the low state ($\epsilon_t = \epsilon_L$) and the ELB is binding;
2. $\tau \leq t < \tau + k_\tau$: the shock has returned to the high, absorbing state ($\epsilon_t = \epsilon_H$) but the ELB is still binding;
3. $\tau + k_\tau \leq t$: the shock remains in the absorbing state ($\epsilon_t = \epsilon_H$) and the ELB is not binding.

At time $t = 1$ a realisation of the shock in the low state hits the system, such that $\epsilon_1 = \epsilon_L$. In period $t = \tau$ the disturbance reverts to the high, absorbing state; and it stays there forever. Note that for each possible τ , the solution proposed above prescribes k_τ additional periods in which the ELB is binding.

As for the inequality constraint, there are a few switching points: first, the inequality constraint is binding

⁷See Fernández-Villaverde, Rubio-Ramírez and Schorfheide (2016) for an overview of solution methods for macroeconomic models, including perturbation methods. Schmitt-Grohé and Uribe (2009) and Judd (1998) are excellent sources for in-depth treatment of perturbation methods.

⁸The exogenous disturbance ϵ_t needs not to be a scalar. As long as the shocks are perfectly correlated, one should think of ϵ_t as a vector of perfectly correlated innovations.

⁹An example of this in the context of the ELB is optimal policy by the central bank under commitment. Here we can split the problem into three regimes, one in which the shock is over and the ELB is slack, one in which the shock is over but the ELB binds, and one in which the shock continues and the ELB binds. Note that not every problem needs to have three (or four) regimes; the problem of the central bank under discretion (without endogenous state variables) typically only requires two regimes.

¹⁰This regime generalises the solution method in Eggertsson and Woodford (2003) to allow for very sluggish policy rules. Notice that \tilde{T} can be 1, meaning that regime 0 never starts. This is the case, for example, of a fully forward-looking economy such as the standard NK model with a policy rule that has no lagged terms.

starting from some point in time \tilde{T} ; this is the switching time from regime 0 to regime 1.¹¹ Note that from the agents' perspective \tilde{T} is known and deterministic. Second, when the shock reverts to its absorbing state at time τ , the inequality constraint could still be binding. This situation constitutes a separate regime, and the switching time is stochastic in nature because it is governed by the Markov process. τ is the switching time from regime 0 or 1 to regime 2. The duration of regime 2 is denoted by k_τ , and it might depend on the duration of the preceding regimes. Finally, $\tau + k_\tau$ represents the time when the economy switches from regime 2 to regime 3, during which the shock is in its absorbing state and the constraint does not bind anymore; regime 3 governs the dynamics thereafter.¹²

To take into account the expectations channel that interlinks the regimes, we solve the problem backwards, starting with regime 3. Since we assume an absorbing state for the exogenous shock, the system is deterministic in regimes 2 and 3. It is in regimes 0 and 1, in which expectations about future realisations of the shock affect current behaviour, that the stochastic setting comes into play.

3.2 General Formulation

To introduce technical notation, many macroeconomic models can be formulated in the following form:

$$\mathbb{E}_t \tilde{f}(\tilde{\zeta}_{t+1}, \tilde{\zeta}_t, \tilde{\epsilon}_t) \leq 0 \quad (1)$$

where $\tilde{\zeta}_t$ is a vector of endogenous variables and $\tilde{\epsilon}_t$ is a (vector) shock following a two-state Markov process with an absorbing state.¹³ The disturbance switches back to the absorbing state with probability 1 at a (deterministic) time, τ_{max} .¹⁴ \mathbb{E}_t is the mathematical operator for expectation conditional on information available at time t and $\tilde{f}(\cdot, \cdot, \cdot)$ is a differentiable function. Typically, \tilde{f} contains structural equations or necessary first order conditions of an optimisation problem in a microfounded economic model. The inequality sign in (1) accounts for the presence of inequality constraints.¹⁵ For the sake of convenience, we transform the notation in (1) as follows:

$$\mathbb{E}_t f^*(\zeta_{t+1}^*, \zeta_t^*) \leq 0 \quad (2)$$

where $\zeta_t^* = [\tilde{\zeta}_t, \tilde{\epsilon}_{t-1}]' = [Z_t^*, S_{t-1}^*, \tilde{\epsilon}_{t-1}]'$ is a vector of $N_Y^* = (N_Z + N_S + N_\epsilon)$ elements, of which N_Z are non-predetermined (or jump) variables Z_t^* , N_S are predetermined variables S_{t-1}^* , and N_ϵ exogenous disturbances $\tilde{\epsilon}_{t-1}$.

In order to cope with the inequality constraints, we split the system into several regimes. In each regime the system of equations can take a different form, so we denote each resulting system by another subscript. Importantly, the inequality constraints are either slack or binding, so that we write a system of equations instead of inequalities. We denote each system of equations by the following, where $i \in \{0, 1, 2, 3\}$

¹¹Notice that the toolkit allows for \tilde{T} to be large enough that regime 1 never starts. This generalises the use of the toolkit for shocks that are small enough to not cause the inequality constraint to bind.

¹²The toolkit in its current version does not allow for a switch from a higher-numbered regime back to a lower-numbered one, for example from regime 1 to regime 0. Some models could require such a feature be possible for a solution to be found, for example in models implying a lot of inertia. We never encountered such a need when working with the toolkit.

¹³This notation requires that exogenous variables appear in present values only.

¹⁴Note that τ_{max} can be set so that the period at which the shock reverts to its high state is arbitrarily far in the future.

¹⁵The full set of first-order conditions usually also includes transversality conditions, no-Ponzi-scheme conditions and initial conditions. For brevity's sake we do not explicitly formulate them. Moreover, note that this formulation is general enough to include higher-order difference equations, since they can be easily transformed into first-order difference equations by redefining $\tilde{\zeta}$.

indicates the regime:

$$\mathbb{E}_t f_i^* (\zeta_{t+1}^*, \zeta_t^*) = 0 \quad (3)$$

Next, we approximate the nonlinear system of equations in (3) to the first order around a specific point. Usually, we approximate it around the deterministic steady state $\bar{\zeta}$ of some baseline regime \bar{i} that fulfils the following conditions:

$$f_i^* (\bar{\zeta}, \bar{\zeta}) = 0 \quad (4)$$

We can linearise around an equilibrium point of any regime, and the choice of point will depend on the application. We can write the resulting linear system of equations in the following general form:

$$A^i \mathbb{E}_t \zeta_{t+1} = B^i \zeta_t \quad (5)$$

where A^i and B^i are $N_Y \times N_Y$ coefficient matrices and $\zeta_t = [Z_t, S_{t-1}, \epsilon_{t-1}, C_t]' = [Z_t, P_{t-1}]'$ is an $N_Y = (N_Y^* + 1) \times 1$ vector.¹⁶ The variables $\zeta_t, Z_t, S_t, \epsilon_t$ and P_t are now written without star because of linearisation, in the process of which the variables are often transformed, for example to log-deviation from steady state. The term C_t accounts for the binding inequality constraint.¹⁷

The solution path to small perturbations that is derived from the linearised system in (5) will be exact only up to a residual of order $\mathcal{O}(\|\epsilon, \bar{\delta}\|^2)$. The $\mathcal{O}(\cdot)$ term is the remainder appearing in the first-order Taylor-series approximation. In addition, ϵ in the big-O expression refers to the perturbation of the shock variable and $\bar{\delta}$ accounts for the fact that the equilibrium in regimes other than the baseline might not coincide with the point we linearise around. This amounts to another perturbation that brings us away from the point we approximate around. In our examples below, we usually have $\bar{\delta} = \frac{i - \bar{i}}{1 + \bar{i}}$, with \bar{i} being the nonstochastic steady-state interest rate. Then we have $\bar{\delta} \neq 0$ if $i = 0$, which is the case in regimes 1 and 2.

As noted in [Eggertsson and Woodford \(2003\)](#), as well as in [Woodford \(2003\)](#) p.383 ff., perturbation theory provides accurate linearised solutions only for shocks in which both ϵ and δ are small. [Eggertsson and Woodford \(2003\)](#) show that we can make $\bar{\delta}$ arbitrarily small by assuming that interest is paid on base money. In our application, $\bar{\delta}$ is close to realistic values (for example, a drop of the interest rate from 3 percent to 0), and we hope (without verifying) that our linear approximation is accurate. [Eggertsson and Singh \(2019\)](#) compare the fully nonlinear version of a standard NK model with a binding ELB to the log-linearised version and find that they behave similarly for reasonable values of disturbances, including ours.

The system in (5) has a familiar form, and we can therefore apply standard rational-expectations solution methods. All regimes except the last have finite duration. [Blanchard and Kahn \(1980\)](#) present the conditions under which a system of infinite horizon, such as (5), has a unique bounded solution. The regimes before the last one have a finite terminal date and can be solved recursively. Solutions take the following form, where G_t^i and D_t^i are transition matrices:

$$P_t = G_t^i P_{t-1} \quad (6)$$

$$Z_t = D_t^i P_t \quad (7)$$

¹⁶The vector P_t contains all predetermined variables, which include past exogenous shocks and constants.

¹⁷When the constraint is not binding we typically have $C_t = 0$. To give a concrete example, consider the zero lower bound and the nominal rate i_t . We can define $\hat{i}_t = \frac{i_t - \bar{i}}{1 + \bar{i}}$. When the zero bound is binding, we have $i_t = 0$ and $\hat{i}_t = -\frac{\bar{i}}{1 + \bar{i}}$. This is an example of a constant term.

We see that time- t variables will be a linear combination of predetermined variables, shocks and constants. Once we find all transition matrices, an initial condition for the predetermined variables P_0 allows us to compute the evolution of the dynamical system.

3.3 The Solution Algorithm

Having outlined our approach, we now show the way to derive the transition matrices of every regime. Because transition matrices of earlier regimes depend on the matrices of later ones, we solve the problem recursively. We first take the length of each regime as given, and we then discuss how to determine vector k and time \tilde{T} . The former contains the length of regime 2 for each realisation of the shock path. We refer to those realisations as *contingencies*.

3.3.1 Finding the transition matrices in all four regimes given k and \tilde{T}

Here we describe the construction of matrices G_t^i and D_t^i for each regime. We rename the matrices according to the following notation, so that the names correspond to the state they are in.

Period t	$t < \tilde{T}$...	\tilde{T}	...	$t < \tau$...	τ	...	$\tau \leq t < \tau + k_\tau$...	$t \geq \tau + k_\tau$
D_t	$D^{0,t}$...	$D^{1,\tilde{T}}$...	$D^{1,t}$...	D^{2,k_τ}	...	$D^{2,j}$...	D^3
G_t	$G^{0,t}$...	$G^{1,\tilde{T}}$...	$G^{1,t}$...	G^{2,k_τ}	...	$G^{2,j}$...	G^3

where $j = k_\tau - (t - \tau)$ denotes how many periods are left until the ELB is no longer binding.

Solution for regime 3: $t \geq \tau + k_\tau$. The system can be written in the following form:

$$A^3 \mathbb{E}_t \begin{bmatrix} Z_{t+1} \\ P_t \end{bmatrix} = B^3 \begin{bmatrix} Z_t \\ P_{t-1} \end{bmatrix} \quad (8)$$

A system of this form can be solved by the method outlined in [Blanchard and Kahn \(1980\)](#) and in [King and Watson \(1998\)](#).

The solution takes the following form:

$$\begin{aligned} P_t &= G^3 P_{t-1} \\ Z_t &= D^3 P_{t-1} \end{aligned}$$

Superscript 3 denotes the regime, and no subscripts are present because D^3 and G^3 do not depend on time.

Solution for regime 2: $\tau \leq t < \tau + k_\tau$. Similarly to the previous case, the system can be written as follows:

$$\begin{aligned} A^2 \mathbb{E}_t \begin{bmatrix} Z_{t+1} \\ P_t \end{bmatrix} &= B^2 \begin{bmatrix} Z_t \\ P_{t-1} \end{bmatrix} \\ \begin{bmatrix} A_1^2 & A_2^2 \\ A_3^2 & A_4^2 \end{bmatrix} \begin{bmatrix} \mathbb{E}_t Z_{t+1} \\ P_t \end{bmatrix} &= \begin{bmatrix} B_1^2 & B_2^2 \\ B_3^2 & B_4^2 \end{bmatrix} \begin{bmatrix} Z_t \\ P_{t-1} \end{bmatrix} \end{aligned} \quad (9)$$

We want to find a solution of the following form:

$$\begin{aligned} P_t &= G^{2,j} P_{t-1} \\ Z_t &= D^{2,j} P_{t-1} \end{aligned}$$

We show how to derive these matrices in Lemma 1.

Lemma 1. Let \tilde{A} be the reduced row echelon form of \tilde{B} , where

$$\tilde{A} = \begin{bmatrix} I & 0 & -C_1 & -C_2 \\ 0 & I & -C_3 & -C_4 \end{bmatrix} \quad \text{and} \quad \tilde{B} = \begin{bmatrix} A_2^2 & -B_1^2 & -B_2^2 & A_1^2 \\ A_4^2 & -B_3^2 & -B_4^2 & A_3^2 \end{bmatrix}$$

The solution in regime 2 will be the following:¹⁸

$$\begin{aligned} G^{2,j} &= \left[I - C_2 D^{2,j-1} \right]^{-1} C_1 \\ D^{2,j} &= C_3 + C_4 D^{2,j-1} G^{2,j} \end{aligned}$$

Also, it will hold true that $D^{2,0} = D^3$ and $G^{2,0} = G^3$

Proof. See appendix A.1. □

Solution for regime 1: $t < \tau$. Similarly to regime 2, we can write the solution in the following form:

$$\begin{bmatrix} A_1^1 & A_2^1 \\ A_3^1 & A_4^1 \end{bmatrix} \begin{bmatrix} \mathbb{E}_t Z_{t+1} \\ P_t \end{bmatrix} = \begin{bmatrix} B_1^1 & B_2^1 \\ B_3^1 & B_4^1 \end{bmatrix} \begin{bmatrix} Z_t \\ P_{t-1} \end{bmatrix} \quad (10)$$

Note that the transition matrices are now time varying, because in regime 1 the expectations at time t depend on k_{t+1} , in turn because $E_t Z_{t+1} = \mu Z_{t+1} | \epsilon_{t+1} = \epsilon_L + (1 - \mu) Z_{t+1} | \epsilon_{t+1} = \epsilon_H = \mu D_{t+1}^1 P_t + (1 - \mu) D^{2,k_{t+1}} P_t \equiv \check{D}_t^1 P_t$. Recall that with probability μ the shock will stay in the low state, while with probability $1 - \mu$ the shock will switch back to the high state and the coefficient matrix D will be calculated according to the next regime.

Let \tilde{C}_t be the reduced row echelon form of \tilde{D}_t , where:

$$\tilde{C}_t = \begin{bmatrix} I & 0 & -C_{t,1} & -C_{t,2} \\ 0 & I & -C_{t,3} & -C_{t,4} \end{bmatrix} \quad \text{and} \quad \tilde{D}_t = \begin{bmatrix} A_{t,2} & -B_{t,1} & -B_{t,2} & A_{t,1} \\ A_{t,4} & -B_{t,3} & -B_{t,4} & A_{t,3} \end{bmatrix}$$

Then, we can rewrite the system as follows:

$$\begin{bmatrix} P_t \\ Z_t \end{bmatrix} = \begin{bmatrix} C_{t,1} & C_{t,2} \\ C_{t,3} & C_{t,4} \end{bmatrix} \begin{bmatrix} P_{t-1} \\ \mathbb{E}_t Z_{t+1} \end{bmatrix} = \begin{bmatrix} C_{t,1} & C_{t,2} \\ C_{t,3} & C_{t,4} \end{bmatrix} \begin{bmatrix} P_{t-1} \\ \check{D}_t^1 P_t \end{bmatrix} \quad (11)$$

¹⁸Given the deterministic nature of regimes 2 and 3, we ignore the expectation term.

Once again, we want to find a solution of the following form:

$$\begin{aligned} P_t &= G^{1,t} P_{t-1} \\ Z_t &= D^{1,t} P_{t-1} \end{aligned}$$

To solve for these matrices we assume that at some time τ_{max} the probability of the shock returning to its absorbing state (given that this did not happen at time $\tau_{max} - 1$) is no longer $1 - \mu$, but 1. This allows us to use the same solution strategy as in regime 2 to obtain the following:

$$\begin{aligned} G^{1,\tau_{max}-1} &= \left[I - C_2 D^{2,k_{\tau_{max}}} \right]^{-1} C_{\tau_{max},1} \\ D^{1,\tau_{max}-1} &= C_3 + C_4 D^{2,k_{\tau_{max}}} G^{1,\tau_{max}-1} \end{aligned}$$

We can apply this methodology recursively for $t < \tau_{max} - 1$:

$$\begin{aligned} G^{1,t} &= \left[I - C_{t,2} \check{D}_t^1 \right]^{-1} C_{t,1} \\ D^{1,t} &= C_{t,3} + C_{t,4} \check{D}_t^1 G^{1,t} \end{aligned}$$

Solution for regime 0: $t < \tilde{T}$. The solution for regime 0 follows the same procedure as the one for regime 1. The only difference is that the matrices A and B differ from those in regime 1. Regime 0 holds until time $t = \tilde{T}$. The transition matrices in regime 0 have the following form:

$$\begin{aligned} G^{0,t} &= \left[I - C_{t,2} \check{D}_t^0 \right]^{-1} C_{t,1} \\ D^{0,t} &= C_{t,3} + C_{t,4} \check{D}_t^0 G^{0,t} \end{aligned}$$

So far we have considered the vector k (the duration of regime 2 for each and every τ) and the scalar \tilde{T} (the period in which regime 1 starts holding) to be known by the agents of the economy. The next sections explain the algorithm we use to find k and \tilde{T} .

3.3.2 Finding k given \tilde{T}

The algorithm to find k for a given \tilde{T} is straightforward: we start from a vector of zeros, meaning that regime 2 is believed not to exist, under any contingency. We then use the transition matrices described in the previous section and trace the evolution of all variables, including the one constrained with inequality (for example, the nominal interest rate). Starting from the first contingency, we then check whether the inequality constraint is violated in the first period of regime 3. If it is not violated, we move forward to the next contingency and the next until we encounter a contingency for which, according to the transition matrices, the inequality is violated in the first period of regime 3. Whenever we find such a contingency, we update k by adding one unit to the duration of regime 2 under that contingency.

In the interest of saving computing power, it is possible to assume that there is an increasing relationship between the number denoting a specific contingency and the length of regime 2. Such an assumption is harmless in some models, but we have yet to show that the results are not affected in general. If one wants to verify that a given k does indeed imply a solution to the dynamic system, it is possible to check that the necessary condition on the variable whose constraint is potentially binding is not violated.¹⁹

¹⁹This situation arises, for example, when a Taylor rule prescribes a negative nominal interest rate or – as in [Eggertsson and](#)

Having updated k , we proceed as explained in the previous sections by calculating a new set of transition matrices and then we follow the algorithm outlined above to check whether there is some contingency for which the inequality is violated in the first period of regime 3.²⁰

3.3.3 Finding \tilde{T}

The algorithm to find \tilde{T} is intuitive. For a given \tilde{T} – say, T (which is initialised at 1) – we take two steps to check whether it is the solution: first, for $\tilde{T} = T$, meaning that regime 1 starts at time T , we check that the inequality constraint is *not* violated at $t = T - 1$; second, we impose $\tilde{T} = T + 1$, assuming that regime 1 starts at $T + 1$. We find the corresponding k , simulate the economy forward, and finally check whether the inequality constraint *is* violated for $t = T$. If the inequality constraint is indeed violated, then regime 1 should start at $t = T + 1 - 1 = T$ and we conclude that $\tilde{T} = T$. If the inequality constraint is not violated for $t = T$, this implies that regime 0 is correctly imposed in $t = T + 1$. In such a case, we continue iterating by increasing T by one.

4 Applications

As an application, we revisit Eggertsson and Woodford (2003), henceforth EW2003, and analyse the optimal monetary policy at the ELB in the standard NK model. We then ask what kind of policy rule can implement it. Our key finding is that EW2003 suggests a *simplified* price level targeting rule, which performs poorly in replicating the optimal commitment policy in numerical experiments in which the price level does not drop much at the ELB. We consider this scenario because of its similarity to the Great Recession in the United States and because it stands in stark contrast with the experiment considered in EW2003. We also show that popular policy proposals such as nominal GDP targeting do relatively poorly in simulations in which the price level does not fall significantly at the ELB. We explain the logic of this result and suggest new alternative policy rules that do better. Finally, we confirm that the insights from the numerical experiments in the standard two-equation NK model extend to a medium-scale quantitative model, such as the one used by the Federal Reserve Bank of New York.

4.1 The Optimal Commitment Policy in Eggertsson and Woodford (2003)

EW2003 presents the standard two-equation NK model and analyses the optimal monetary policy under commitment (OCP) in the context of the ELB. The policy can be represented by the following set of

Woodford (2003) – when the Lagrange multiplier is correctly non-negative.

²⁰Following this procedure, it is possible to find a k that solves the dynamic system with binding constraints. The existence of a k does not imply its uniqueness. However, we never found multiple solutions to the same problem when applying our solution method.

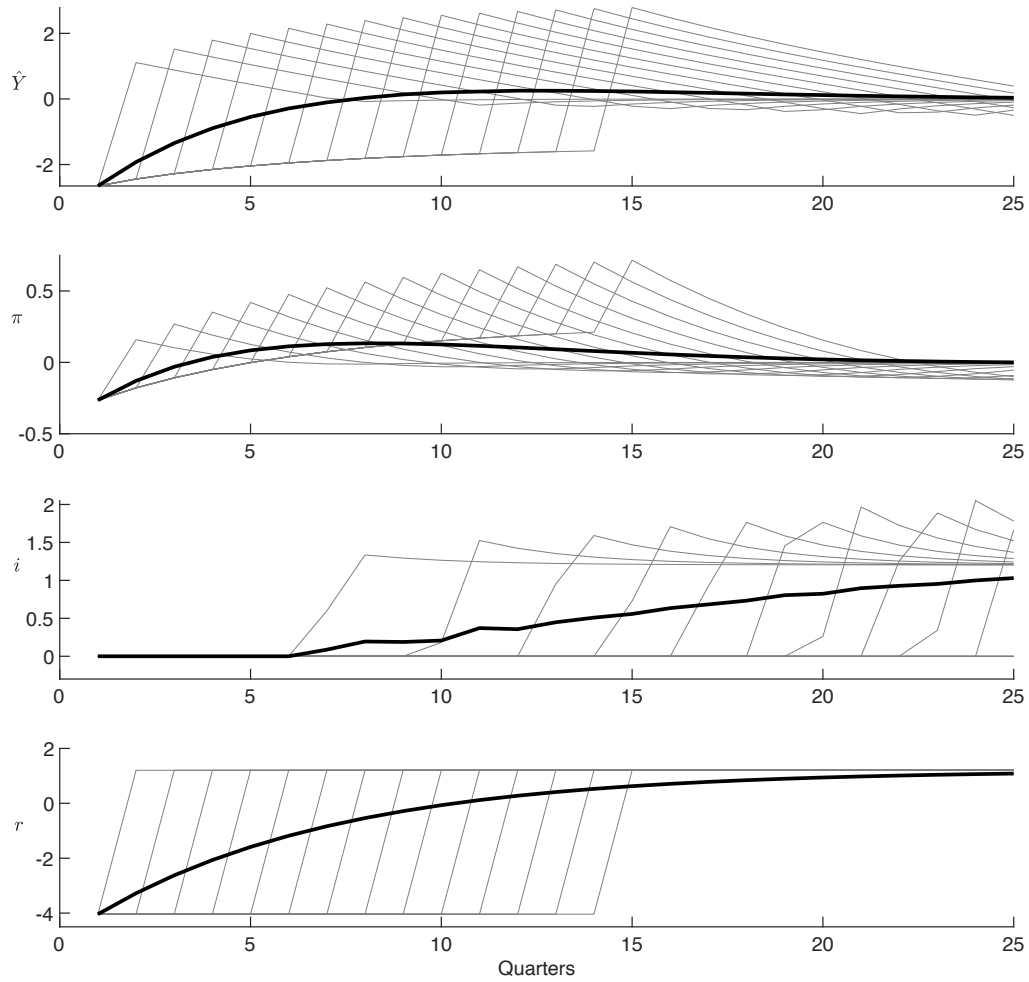

Figure 1: Optimal Commitment Policy as in [Eggertsson and Woodford \(2003\)](#). Bold lines are the impulse response for output (\hat{Y}), inflation (π), the nominal interest rate (i), and natural rate (r^n), grey lines represent the evolution for single contingencies (from 2 to 15). The vertical axes report deviations from steady state, in percentage points (annualised). The vertical axis for the interest rate reports annualised percentage points.

equations:²¹

$$\hat{Y}_t = \mathbb{E}_t \hat{Y}_{t+1} - \sigma(i_t - \mathbb{E}_t \hat{\pi}_{t+1} - r_t^n) \quad (12)$$

$$\hat{\pi}_t = \kappa \hat{Y}_t + \beta \mathbb{E}_t \hat{\pi}_{t+1} \quad (13)$$

$$0 = \hat{\pi}_t + \phi_{2t} - \phi_{2t-1} - \frac{1}{\beta} \sigma \phi_{1t-1} \quad (14)$$

$$0 = \lambda \hat{Y}_t + \phi_{1t} - \frac{1}{\beta} \phi_{1t-1} - \kappa \phi_{2t} \quad (15)$$

$$\phi_{1t} \geq 0 \quad (16)$$

$$i_t \geq 0 \quad (17)$$

$$\phi_{1t} i_t = 0 \quad (18)$$

where \hat{Y}_t is output in deviation from steady state, $\hat{\pi}_t$ is inflation, i_t is the nominal interest rate, ϕ_{1t} and ϕ_{2t} are Lagrange multipliers, and r_t^n is an exogenous disturbance – the natural rate of interest – that follows a two-state Markov process. Specifically, there is an unexpected reduction in the natural rate of interest in period 1 so that $r_1^n = r_L^n < 0$, and

$$r_{t>1}^n = \begin{cases} r_L^n & \text{w.p. } \mu & \text{if } r_{t-1}^n = r_L^n \\ r_H^n & \text{w.p. } 1 - \mu & \text{if } r_{t-1}^n = r_L^n \\ r_H^n & & \text{if } r_{t-1}^n = r_H^n \end{cases} \quad (19)$$

The toolkit simulates the economy described above and produces the outputs as shown in Figure 1, which replicates the results in EW2003. In the online guide, we outline the steps required for coding the simulation. Each of the light grey lines represents a contingency. Note that the period in which the exogenous disturbance switches to its absorbing state is sufficient to characterise the specific realisation of the Markov process. For this reason, one can describe a contingency as the period in which the exogenous shock returns to its steady state. For example, the grey line third from the left in the panels for inflation, output and interest rates corresponds to the case in which the natural rate of interest reverts to its steady state in period $t = 4$. Observe that the evolution of a variable in a given contingency, prior to the shock's reversion to steady state, depends on expectations about the evolution of variables in all future contingencies. The bold lines represent impulse response functions – weighted averages of the evolution of each variable that correspond to the expectation agents have about the economy in the initial period after the shock is realised.

4.2 Implementing the Optimal Commitment in Eggertsson and Woodford (2003) via a Price Level Target and a Nominal GDP Target

In Figure 2 we compare the OCP to the standard Taylor rule (TTR) using the numerical values assumed in EW2003. As emphasised in that paper, the Taylor rule, or equivalently a strict inflation target, results in a large output drop (about 15 percent) and drop in inflation (about 10 percent) at the ELB. Via the central bank's commitment to keeping the nominal interest rate low for a substantial period, the OCP eliminates most of the drop in output. EW2003 also shows that a policy rule that fully implements this equilibrium can be described as follows: at the ELB, the central bank commits to not increasing the

²¹See Eggertsson and Woodford (2003) for more details on the derivation. We use the EW2003 parameterisation: $\theta = 7.87$, $\sigma = 0.5$, $\kappa = 0.02$, $\beta = 0.99$, $\lambda = \frac{\kappa}{\theta}$, $\mu = 0.9$, $r_L^n = -0.005$, $r_H^n = \beta^{-1} - 1$.

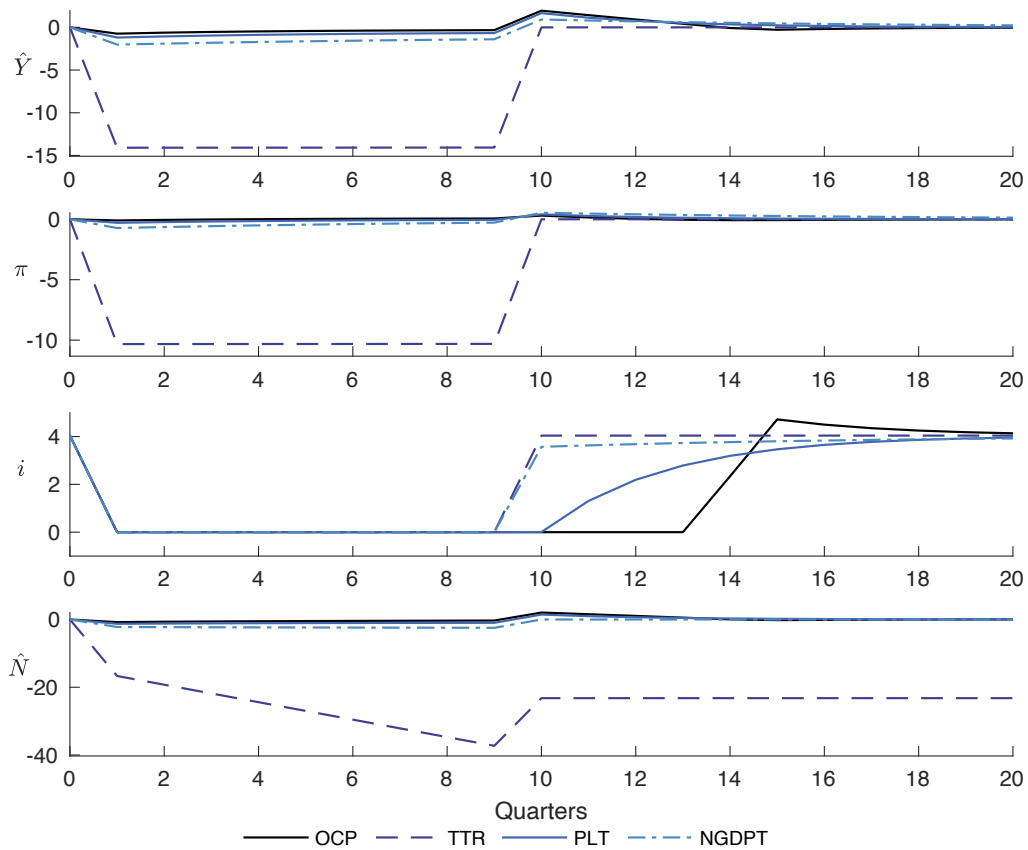

Figure 2: Selected rules and optimal commitment (OCP) under Eggertsson and Woodford (2003) calibration. Lines represent contingency 10 for output (\hat{Y}), inflation (π), the nominal interest rate (i), and nominal GDP (\hat{N}). The vertical axes report deviations from steady state, in percentage points (annualised figures). The vertical axis for the nominal interest rate reports annualised percentage points.

interest rates unless an index \tilde{P}_t reaches a certain threshold \hat{P}_t^* , that is $\tilde{P}_t = \hat{P}_t^*$ – where \tilde{P}_t is an index built as a weighted average of (detrended) output (\hat{Y}_t) and the (detrended) price index (\hat{P}_t):

$$\tilde{P}_t \equiv \hat{P}_t + \frac{\kappa}{\lambda} \hat{Y}_t \quad (20)$$

The key to this commitment is how the threshold \hat{P}_t^* is formulated. EW2003 shows that the optimal monetary policy commitment is replicated when \hat{P}_t^* is computed according to the following formula:

$$\hat{P}_{t+1}^* = \hat{P}_t^* + \beta^{-1}(1 + \kappa\sigma)\Delta_t - \beta^{-1}\Delta_{t-1} \quad (21)$$

where Δ_t measures the amount by which the monetary authority misses its target in period t because of the ELB:

$$\Delta_t \equiv \hat{P}_t^* - \tilde{P}_t \quad (22)$$

The authors of EW2003 recognise that this rule might be difficult to communicate in practice. Hence, they suggest a simplified variation of the optimal rule:

$$\hat{P}_t + \frac{\kappa}{\lambda} \hat{Y}_t = \hat{P}^* \quad \forall t \quad (23)$$

Now the gap-adjusted price level target (PLT) is fixed at all times. Figure 2 shows that this simplified policy rule does a relatively good job at replicating the OCP. The reason is that the fall in the price level over the course of the shock induces the central bank to promise a policy easing once the disturbance has subsided. Thus, the interest rate remains at its lower bound even after the shock has reversed, and inflation and the output gap could be set at their steady-state values. This is the key feature of the optimal policy commitment. As stressed by [Woodford \(2012\)](#), targeting nominal GDP instead of the price level has the same essential features. This kind of policy has been suggested by a number of authors, such as [Hatzius and Stehn \(2011\)](#) and [Sumner \(2012\)](#). A nominal GDP target (NGDPT) can be written as follows:

$$\hat{P}_t + \hat{Y}_t = \hat{Y}^* \quad (24)$$

This is equivalent to the simplified price level target in EW2003 for special values of λ . Figure 2 shows that this policy does a relatively good job in replicating the OCP in the EW2003 numerical example.

4.3 The Great Recession and the Robustness of Nominal GDP Targeting and a Price Level Targeting

The key take-away from the last section is that the simple price level target suggested in EW2003 and the nominal GDP target replicate the optimal commitment policy relatively well in the EW2003 numerical example. As we discussed, this is because the fall in the price level generates a commitment to lowering future nominal interest rates once the shock has reverted to its steady state, while a standard Taylor rule would imply immediately normalising rates.

A key feature of the EW2003 calibration, however, is that if one assumes standard policy rules, such as the Taylor rule, the price level falls substantially by about 10 percent per year, as shown in Figure 2. Meanwhile, in the Great Recession in the United States, the fall in the price level was much smaller by most accounts. Inflation – as measured by personal consumption expenditures, for example – averaged about 1.5 percent from 2008 to 2015, when the Federal Reserve started raising rates, which is only 0.5

percent below its 2 percent inflation target. This is in sharp contrast to the 10 percent drop in inflation predicted by the EW2003 parametrisation.

We now analyse the performance of the PLT and NGDPT rules after calibrating the model to match the smaller drop in inflation. For this experiment, we interpret²² inflation as the deviation of inflation from target, as in [Benigno, Eggertsson and Romei \(2020\)](#).²³

To parameterise the model, we calibrate κ and σ as in EW2003. Moreover, we assume the presence of a cost push shock u_t that is perfectly correlated with the natural rate of interest and thus follows the same two-state Markov process we have already discussed.²⁴ We then set both r_L and u_L to match a drop in inflation of 0.5 percent and output of 7.5 percent, thus taking on different values than those in EW2003.²⁵ A key assumption is that policy was conducted according to a standard Taylor rule in this period. This calibration strategy results in $r_L = -0.013875$ and $u_L = 0.00136375$.

The idea behind the calibration is that the shock that gave rise to the Great Recession – for example, a debt-deleveraging shock or a similar displacement originating in the financial sector – simultaneously led to a cost push and a drop in the natural rate of interest. While we model this in a reduced form, it is also the explanation given for the lack of deflation during the Great Recession in [Eggertsson and Krugman \(2012\)](#), who derive a fully specified microfoundation.²⁶ Our approach is also consistent with the estimated DSGE model in [Christiano, Eichenbaum and Trabandt \(2015\)](#).

As an alternative to choosing a cost push shock to match the limited drop in inflation, we experiment with different values of κ , the slope of the New Keynesian Phillips curve (13), that generate the small drop in inflation observed in the data. We show in section 4.9 that our conclusions are robust to this alternative strategy.

We also change the EW2003 calibration in another important respect. The objective of the central bank in EW2003 is as follows:

$$\mathbb{E}_0 \sum_{t=0}^{\infty} \beta^t [\hat{\pi}_t^2 + \lambda \hat{Y}_t^2] \quad (25)$$

A well-known feature of the standard NK model is that it places virtually no weight on output in the welfare objective of the government. In the EW2003 calibration, while the weight on the squared deviation of inflation from target is 1, the weight on output is only $\lambda = \kappa/\theta = 0.0025$. Here instead we assume equal weights for annual inflation and output, so that $\lambda = 1/16$.

The reason for this alternative assumption is two fold: first, the Federal Reserve typically describes itself as adhering to a dual mandate, with inflation being only one component and some measure of economic activity being the other. These two objectives are typically put on equal footing. Thus, one could argue that an equal weight better captures the behaviour of the Fed in practice. Second, recent research suggests that once one incorporates realistic idiosyncratic shocks in firms' pricing decisions, the weight on output relative to inflation increases substantially. [Eggertsson and Inui \(2020\)](#) show how to microfound a loss function that puts equal weight on inflation and output (other examples in this literature are [Burstein](#)

²²To be consistent with the previous section, we stick to the [Eggertsson and Woodford \(2003\)](#) calibration of $\beta = 0.99$ and $\bar{\pi} = 0$, which implies a steady state real and nominal rate of 4%. Numerical results are almost unchanged if we set $\beta = 0.995$ and $\bar{\pi} = 2\%$, implying a real rate of 2% and a nominal rate of 4%.

²³See [Benigno, Eggertsson and Romei \(2020\)](#) for the microfoundations of price setting for this interpretation.

²⁴Equation (13) becomes $\hat{\pi}_t = \beta \mathbb{E}_t \hat{\pi}_{t+1} + \kappa \hat{Y}_t + u_t$.

²⁵The rationale for these values is discussed in [Eggertsson and Egiev \(2020\)](#).

²⁶In that paper, a cost push is traced back to the effect of the debt-deleveraging shock on the labour supply of borrowers and savers.

and Hellwig 2008 and Nakamura et al. 2018).

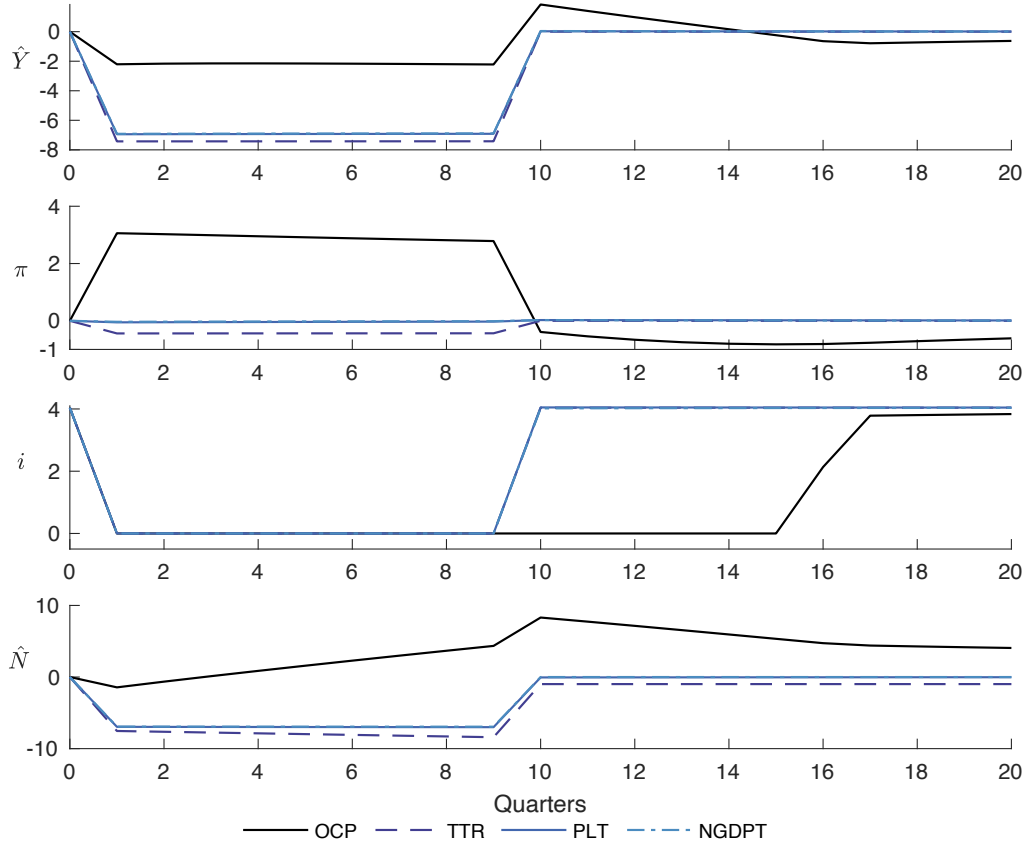

Figure 3: Selected rules and optimal commitment (OCP) under the baseline calibration with cost push shock. Lines are contingency 10 for output (\hat{Y}_t), inflation (π), the nominal interest rate (i), and nominal GDP (\hat{N}). The vertical axes report deviations from steady state, in percentage points (annualised figures). The vertical axis for the nominal interest rate reports annualised percentage points. The list of acronyms is detailed in Table 1.

Figure 3 contrasts the optimal policy commitment (OCP) to the Taylor rule (TTR) under our main calibration strategy, showing the contingency in which the natural rate of interest reverts back to its steady state ten quarters after the shock hits (other contingencies look qualitatively similar). Assuming the Federal Reserve follows a Taylor rule implies, by construction, a fall in inflation of 0.5 percent and a drop in output of 7.5 percent. The OCP, in contrast, results in only a 2 percent drop in output and, instead of falling, inflation overshoots its target substantially throughout the duration of the shock. The central bank accomplishes this by committing to keeping the nominal interest rate at the ELB for about six additional quarters after the natural rate normalises, a similar commitment to that in the original EW2003 example. This commitment now implies that during the crisis period, inflation overshoots its target by about 3 percentage points and then mildly undershoots it once the disturbance subsides. This is in sharp contrast to the EW2003 calibration, in which there is no overshooting of the inflation target when the shock hits. The reason for the different result is that the central bank is now putting output deviation and inflation on equal footing in its objective function. Accordingly, it is more willing to tolerate higher inflation in order to achieve better output stabilisation.

Figure 3 also shows the outcome if the central bank follows a price level target (PLT) of the form suggested by EW2003 and a nominal GDP target (NGDPT). As the figure shows, this commitment does not substantially improve the outcome relative to the Taylor rule. The reason is that the small decrease in the price level in this numerical experiment leads to a trivial additional commitment to low future

rates once the shock subsides. The key mechanism explaining why the PLT succeeds in replicating the OCP in the EW2003 calibration is that the shock generates enough deflation. This means that once the disturbance is over, the central bank does not raise the interest rate for a considerable period – not until the price level returns to the target. If the price level falls very little, the PLT commitment loses most of its power. As it can be seen in the third panel, the nominal interest rate is almost the same for the Taylor rule relative to the PLT or the NGDPT. Note that this problem is exacerbated by the fact that once a central bank commits to either of these two policies, the equilibrium drop in the price level is even smaller than under the Taylor rule, thus implying an even-smaller commitment to future expansion once the shock reverts to its steady state.

A stark assumption in our calibration of the Markov process is that the Federal Reserve followed a Taylor rule during the crisis. This assumption implies that the central bank’s forward guidance during the crisis did not commit it to keeping future rates lower as inflation started to recover. By contrast, if we calibrate the model under the other extreme assumption – that policy was conducted under optimal commitment – then the implied fall in the price level would have been larger under alternative policy regimes, such as the Taylor rule, and thus PLT or NGDPT would have worked better. We prefer our specification, however, as it more clearly highlights possible pitfalls of these targeting strategies. They critically rely upon a sizeable fall in inflation in order to generate any meaningful commitment to low future rates. In the presence of cost push shocks, or very low values for κ , there is no reason to expect such a fall in the price level from the perspective of the model.

4.4 Cumulative Nominal GDP Targeting and Symmetric Dual-Objective Targeting

We now consider simple alternatives to the price level and nominal GDP targeting rules that better replicate the optimal commitment policy.

The key problem with both rules is that if the price level does not decline much, neither rule implies much accommodation once the shock giving rise to the ELB normalises. The OCP, instead, mandates that if there is a decrease in either output or the price level for the duration of the ELB, then there should be accommodation (or *make-up* accommodation) once the crisis period is over, as seen in the analytic derivation of the fully optimal targeting rule. In that derivation, the time-varying target is defined in terms of the weighted average of the price level and output. Moreover, if the target is missed, the fully optimal rule suggests that the future target should be increased, thus generating expectations of future accommodation.

Motivated by this observation, we first consider the following simple targeting rule.²⁷ Define $\hat{\Gamma}_t$ as the cumulative deviation of nominal GDP from its trend:

$$\hat{\Gamma}_t = \hat{P}_t + \hat{Y}_t + \hat{\Gamma}_{t-1} \quad (26)$$

This variable measures how much nominal GDP deviates from its target. Relative to previous NGDPT proposals, such as those discussed above, this variable not only keeps track of the size of deviations of current nominal GDP from its trend, but also accounts for *past misses*. The proposed targeting rule is then to set the nominal interest rate so that cumulative nominal GDP is on trend – that is $\hat{\Gamma}_t = 0$ – whenever possible. Otherwise, the central bank should set the nominal rate at its ELB, with the threshold for lift-off being that the cumulative nominal GDP target is reached again. Critically, if this rule is credible, the public understands that if the Federal Reserve misses its nominal GDP target, it is then committed to

²⁷This rule is closely related to [Reifschneider and Williams \(2000\)](#), section 4.5.

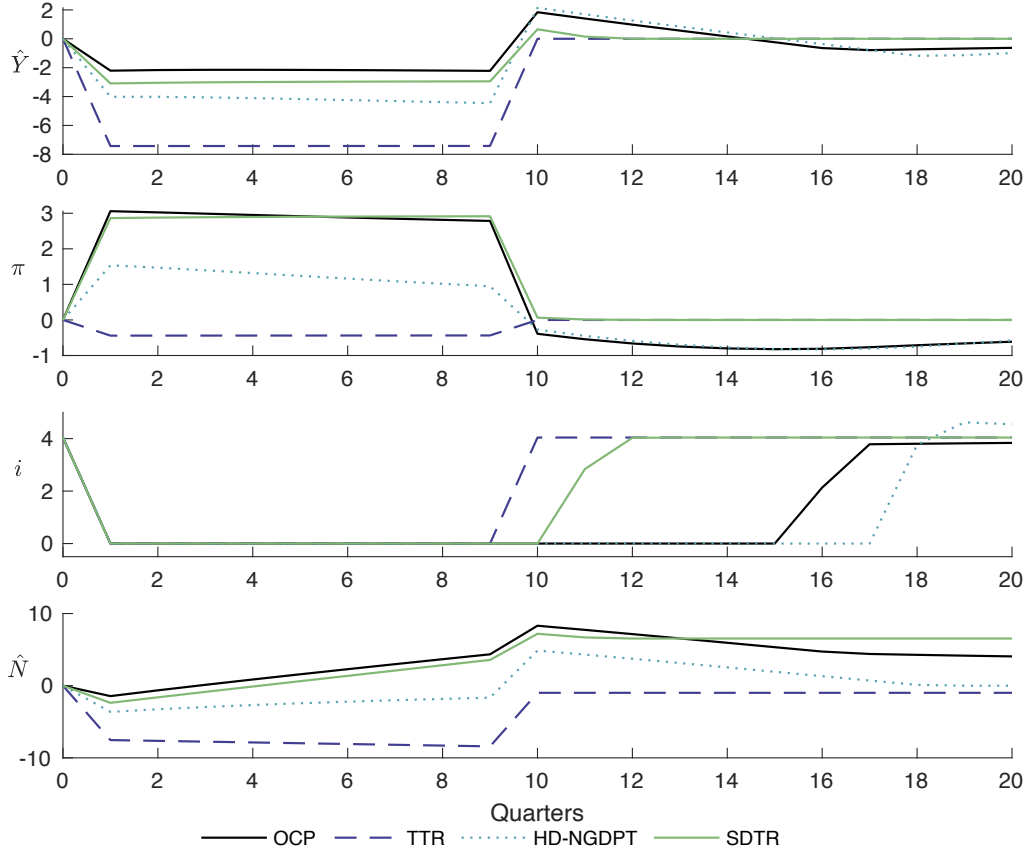

Figure 4: Selected rules and optimal commitment (OCP) under baseline calibration with cost push shock. Lines are contingency 10 for output (\hat{Y}), inflation (π), the nominal interest rate (i), and nominal GDP (\hat{N}). The vertical axes report deviations from steady state, in percentage points (annualised figures). The vertical axis for the nominal interest rate reports annualised percentage points. The list of acronyms is detailed in Table 1.

keeping the interest rate at zero until it has compensated for having missed its target. Thus, if it were to undershoot by 5 percent, it would be committed to overshooting trend nominal GDP by 5 percent going forward.

Figure 4 shows how this target, the *history-dependent nominal GDP target* (HD-NGDPT) does in the numerical experiment. It does substantially better than the PLT or NGDPT as reported in Figure 3 (we provide a more detailed assessment of this comparison in Table 2). The key to the success of this rule is that it prescribes a substantial easing once the ELB is no longer binding on account of the exogenous shock, much as prescribed by the OCP.

As an alternative to keeping track of how nominal GDP falls short of its trend, we also consider the following rule.²⁸ Let us define an index (\hat{D}_t) that measures how inflation and real output deviate from trend:

$$\hat{D}_t = 4\hat{\pi}_t + \hat{Y}_t + \hat{D}_{t-1} \quad (27)$$

A targeting rule we call the *symmetric dual-objective targeting rule* (SDTR) sets interest rates so that what we call the *dual mandate index* (\hat{D}_t) is set to zero if possible but keeps the nominal interest rate at the ELB otherwise.²⁹ Critically then, if a central bank following this reaction function misses its target, it will automatically commit to a future accommodation.

Figure 4 shows the performance of this rule and illustrates that it does even better than the cumulative nominal GDP target (HD-NGDPT). Again, the key to this success is that the rule implies considerably more easing once the ELB is no longer binding than price or nominal GDP targets. The PLT and NGDPT imply *make-up* behaviour for past misses of the inflation target only. The two new rules show this feature as well, but in addition they do the same for output: if there is a recession today, the central bank commits to a boom in the future. This type of commitment is particularly important when the price level moves by a small amount.

The fact that SDTR does better than HD-NGDPT is not robust once we consider a richer model such as the FRBNY DSGE. Before doing that, however, we compare the two proposed rules to other well-known policy rules and offer a more detailed assessment of their performance.

4.5 Comparison to Other Policy Rules

In this section we compare the two policy rules we have suggested to several reaction functions that have been proposed in the literature (Table 1). We summarise their performance in Table 2, using the welfare criterion specified in equation (25), as well as other measures. The first column shows the welfare loss implied by these different rules, with the optimal monetary policy commitment normalised to one.

Of the rules considered, the two we have introduced in section 4.4 are among the best-performing ones, together with the augmented Taylor rule (ATR) proposed by Reifschneider and Williams (2000) and the superinertial Taylor rule (SUP) described in Rotemberg and Woodford (1999). Figure 5 depicts the dynamic response of the simple two-equation model under these different reaction functions, alongside two benchmarks: the OCP and a truncated Taylor rule (TTR). We discuss each one in turn.

The ATR is closely related to our two proposals. According to this rule, a *cumulative* index (Z_t) keeps track of the amount by which the actual interest rate *misses* the interest rate suggested by the standard

²⁸The rule is closely related to Reifschneider and Williams (2000), section 4.5 and rules that feature a lagged interest rate, as in Taylor and Williams (2010) or Kiley and Roberts (2017).

²⁹The inflation gap is multiplied by 4 to make sure that there is equal weight on *annualised* inflation and output.

Name Acronym	Rule
Taylor Rule (TTR)	$i_t^{TTR} = \max \{0, \bar{r} + \bar{\pi} + \phi_\pi \hat{\pi}_t + \phi_y \hat{Y}_t\}$
TR with lag (TTR-1)	$i_t^{TTR-1} = \max \{0, \bar{r} + \bar{\pi} + \phi_\pi \hat{\pi}_{t-1} + \phi_y \hat{Y}_{t-1}\}$
TR with lead (TTR+1)	$i_t^{TTR+1} = \max \{0, \bar{r} + \bar{\pi} + \phi_\pi (E_t \hat{\pi}_{t+1} + \phi_y E_t \hat{Y}_{t+1})\}$
Interest Smoothing (TTRS)	$i_t^{TTRS} = \max \{0, \phi_i i_{t-1} + (1 - \phi_i) (\bar{r} + \bar{\pi} + \phi_\pi \hat{\pi}_t + \phi_y \hat{Y}_t)\}$
Price Level Rule (TTRP)	$i_t^{TTRP} = \max \{0, \bar{r} + \bar{\pi} + \phi_p \hat{P}_t + \phi_y \hat{Y}_t\}$
Nominal GDP Target (NGDPT)	$i_t^{NGDPT} [\hat{P}_t + \hat{Y}_t] = 0$
Augmented Taylor Rule (ATR)	$i_t^{ATR} = \max \left\{ 0, i_t^{TTR} - \alpha Z_t \right\}, \quad i_t^{TTR} = \bar{r} + \bar{\pi} + \phi_\pi \hat{\pi}_t + \phi_y \hat{Y}_t$ $Z_t = Z_{t-1} + \left(i_t^{ATR} - i_t^{TTR} \right)$
Superinertial Taylor Rule (SUP)	$i_t^{SUP} = \max \{0, (1 - \phi^{SUP})(\bar{r} + \bar{\pi}) + \phi^{SUP} i_{t-1} + \phi_\pi \hat{\pi}_t + \phi_y \hat{Y}_t\}$
Average Inflation Targeting (AIT)	$i_t^{AIT} = \max \left\{ 0, \bar{r} + \bar{\pi} + \phi_\pi \hat{\pi}_t + \phi_y \hat{Y}_t + \phi^{AIT} \left(\pi_t^Q - \bar{\pi} \right) \right\}$
Price level target (PLT)	$i_t^{PLT} [\hat{Y}_t + \frac{\kappa}{\lambda} \hat{P}_t] = 0$
History-Dependent NGDP Target (HD-NGDPT)	$\hat{\Gamma}_t i_t^{HD-NGDPT} = 0, \quad \hat{\Gamma}_t = \hat{P}_t + \hat{Y}_t + \hat{\Gamma}_{t-1}$
Symmetric Dual-Objective Targeting Rule (SDTR)	$D_t i_t^{SDTR} = 0, \quad \hat{D}_t = 4\hat{\pi}_t + \hat{Y}_t + \hat{D}_{t-1}$

Table 1: Policy rules, names, and acronyms. π_t^Q is average inflation over last Q quarters. \hat{P}_t is deviation of price level from its (detrended) steady state value. $\hat{\Gamma}_t$ and \hat{D}_t are defined in equation (26) and (27).

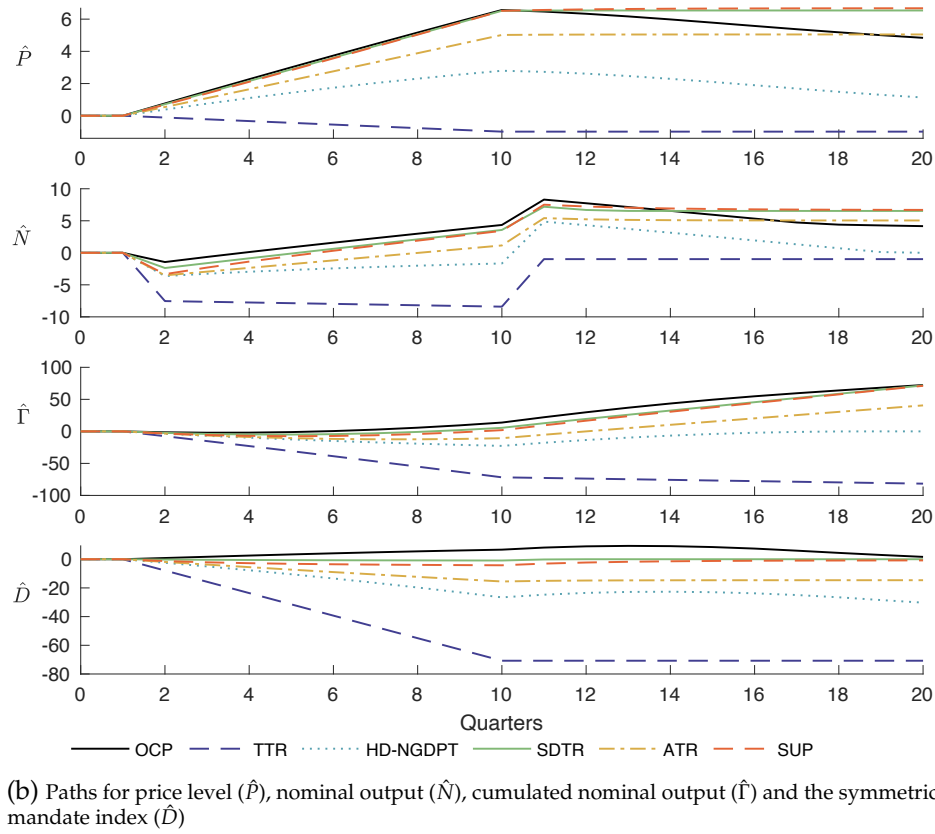

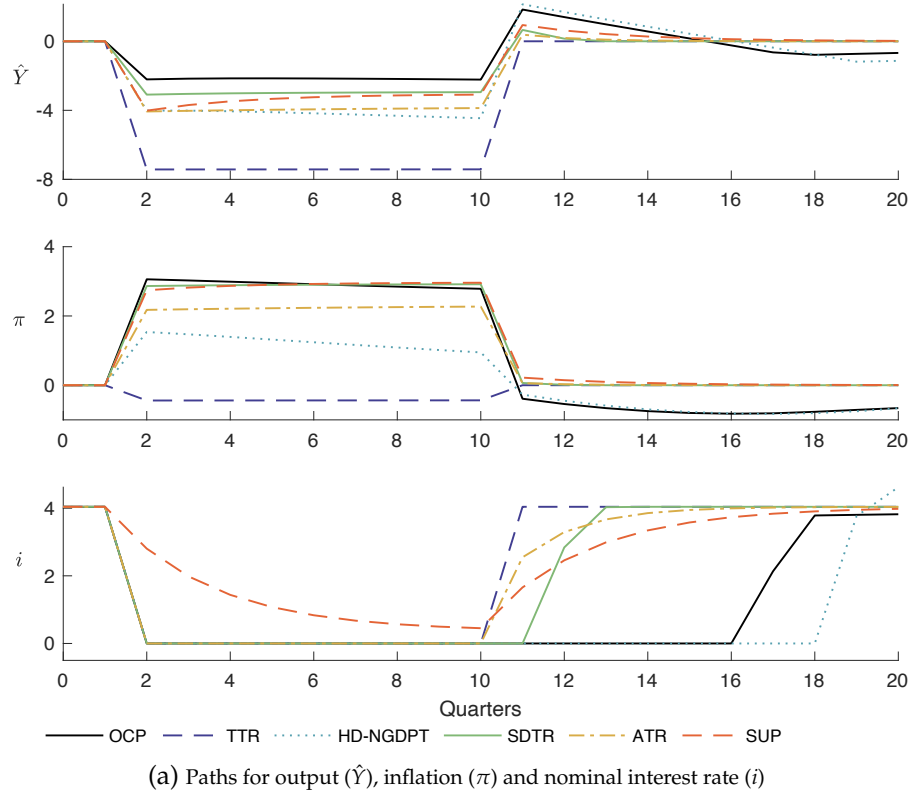

Figure 5: Dynamic response to a natural interest rate shock and a correlated cost push shock in a simple two-equation NK model, under different policy rules. Shocks are calibrated such that output falls by 7.5% and inflation by 0.5% constant under a Truncated Taylor Rule (TTR). The natural interest rate reverts to the absorbing state after 10 quarters (10th contingency). The vertical axes report percentage deviations from steady state (annualised figures). The vertical axis for i reports annualised percentage points. The list of acronyms is detailed in Table 1. The parametrisation is reported in Table A.2. Paths for additional rules reported in Table 1 are shown in section A.6.1 in the appendix.

Taylor rule because of the ELB. This reaction function then prescribes the interest rate to respond to these cumulative misses at a rate α . In turn, this implies that if the ELB is binding, future rates will be lower than predicted by a standard Taylor rule to make up for previous deviations from target. This is a similar *make-up* feature to the one characterising the fully optimal commitment rule in EW2003, and the proposed rules HD-NGDPT and SDTR.

The superinertial rule of Rotemberg and Woodford (1999) generates a similar commitment to low rates for a prolonged period, but for different reasons. As shown in Table 1, it has a lagged interest-rate term appearing in an otherwise-standard Taylor rule. The coefficient on this lagged interest rate, however, is greater than one – hence the word *superinertial*. This implies not only that interest rates drop very slowly in reaction to the shock, as shown in Figure 5, but also that they increase equally sluggishly once the disturbance reverses. This generates exactly the type of commitment needed. Even though this rule does not prescribe an immediate drop in the nominal interest rate in reaction to the shock – as the OCP would mandate – it still outperforms most of the other policy functions under consideration.

In line with the finding of Reifschneider and Wilcox (2019), we document how a Taylor-type rule reacting to average inflation is sub-optimal at best, with a welfare loss comparable to a price level or nominal GDP target. Again, this is mostly because of the limited drop in inflation in this parameterisation of the model. This policy rule is arguably similar to the policy regime adopted by the Federal Reserve in 2020.

Appendix A.5.1 shows the results if we do not impose the ELB and the nominal interest rate is allowed to fall below zero. Our two proposed rules are still among the best-performing ones. Notably, the NGDPT and HD-NGDPT overlap in this case. The central bank can fully stabilise nominal GDP, and thus there will never be a cumulative deviation to be made up for. Further, the PLT performs very well; this should not come as a surprise, as Eggertsson and Woodford (2003) show that the OCP is identical to the PLT if the effective lower bound is never reached.

In the next sections we assess the robustness of these conclusions to different assumptions concerning the size of the inflation response, its source, the choice of policy parameters, as well as how our results transpose to a more sophisticated macroeconomic model.

4.6 Forward Guidance, the Role of Uncertainty and Time-Dependent Policy Commitments

Our toolkit allows us to evaluate the robustness of different policy strategies in the presence of uncertainty. This is particularly helpful for clarifying the difference between *time-dependent forward guidance*, in which the central bank communicates a period when it expects the ELB to be binding, and *state-contingent forward guidance*, in which it stipulates economic conditions – or thresholds – that, once satisfied, allow the interest rate to be lifted above the ELB.

A popular policy strategy followed by policy-makers shortly after the financial crisis of 2007-08 – aimed at providing additional monetary stimulus – was to stipulate that the policy rate would remain at zero until a predetermined calendar time. The Bank of Canada, for example, announced on 21 April 2009 that its policy rate would remain at zero until the end of the second quarter of 2010. The Federal Reserve initially pursued a similar time-dependent strategy by stating that rates would stay low for “some time” (December 2008), for an “extended period” (March 2009) and finally “at least to mid-2013” (August 2011).

While the Bank of Canada and the Federal Reserve did their best to communicate that these time commitments were conditional on incoming data, a common criticism was that the markets interpreted

	Welfare Loss (1)	$\mathbb{E}_0[\tau + k_\tau - \tilde{T}]$ (2)	Volatility \hat{Y} (3)	Volatility π (4)	Volatility i (5)	Impact \hat{Y} (6)	Impact π (7)
OCP	$8.252 \cdot 10^{-4}$	15.257	$5.356 \cdot 10^{-3}$	$4.904 \cdot 10^{-4}$	$1.411 \cdot 10^{-3}$	-2.208	3.059

Table 2: Some metrics for selected interest rate rules in the simple two-equation NK model in the presence of a natural rate shock and a correlated cost push shock. All rows except the first show values normalised with respect to the optimal commitment policy (OCP, first row). Column (1) reports the welfare loss computed from a quadratic loss function (equation 25) for the central bank with equal weights; Column (2) displays the unconditional expected duration of the Effective Lower Bound (regimes 1 and 2); Columns (3)-(5) report a summary measure of deviations of the endogenous variables from target, computed according to equation (A.5); finally, Columns (6) and (7) show the response on impact, in annual percentage points, of the output and inflation to a natural interest rate shock and a correlated cost push shock such that output falls by 7.5 percent and inflation by 0.5 percent under a Truncated Taylor Rule (TTR). Rule calibration reported in Table (A.2). The model is calibrated with the standard EW2003 parameter values reported in footnote 21. The list of acronyms is detailed in Table 1.

this as a binding commitment, regardless of the actual trajectory of the economy [Woodford \(2012\)](#).

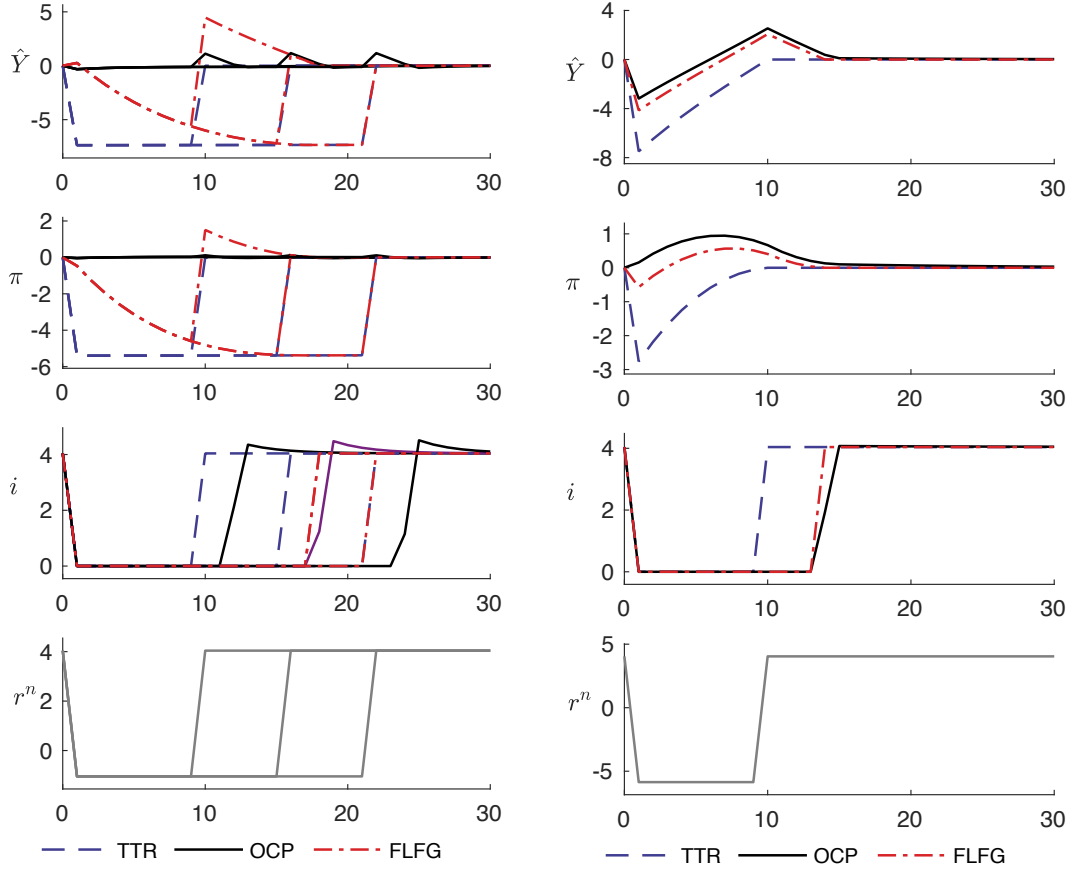

One interpretation of time-dependent forward guidance is that it corresponds to the optimal fixed duration of the zero interest rate determined at time $t = 0$, what we call the optimal *fixed-length forward guidance* (FLFG). Under FLFG, the monetary authority announces that, in response to a negative natural-rate shock, it will hold nominal rates at zero until a fixed calendar date ν , after which the policy will return to a standard Taylor rule. This corresponds to the following policy rule for nominal rates

$$i_t = \begin{cases} 0 & \text{for } t \leq \nu \\ \max(0, \bar{r} + \phi_\pi \pi_t) & \text{otherwise} \end{cases} \quad (28)$$

Figure 6 shows the optimal time-zero FLFG under the assumption of a deterministic process for the natural rate of interest and contrasts it with the optimal policy commitment. As the figure reveals, FLFG approximates the OCP relatively well by mimicking a delayed lift-off of the policy rate.

As stressed by [Woodford \(2012\)](#) however, a key problem with time-dependent forward guidance is that it does not allow the central bank to flexibly react to economic conditions – that is to the shocks that bring the economy to the ELB in the first place. Since our toolkit can incorporate a stochastic duration of the ELB episode, it is ideal for clarifying this point.

Figure 6 compares FLFG with the OCP under the assumption of a two-state Markov process, as in previous sections. As is evident from the figure, FLFG does a much poorer job of replicating the OCP when the duration of the shock is uncertain. The figure shows the realisations for output, inflation,

(a) Natural rate $r^n \sim$ stochastic two-state Markov

(b) Natural rate $r^n \sim$ deterministic two-state Markov

Figure 6: Optimal Fixed-Length Forward Guidance (FLFG, red dot-dash line) under alternative solutions for the two-state Markov natural interest rate disturbance: stochastic (Panel a, left) or deterministic process (Panel b, right). Lines represent impulse responses for output (\hat{Y}), inflation (π), the nominal interest rate (i) and the natural rate (r^n). Panel (a) shows contingency 10, 16 and 22 for each policy rule. At contingency 16, the central bank moves away from the ELB under both optimal commitment (OCP) and fixed-length forward guidance (FLFG). The size of the Markov shock process is calibrated to achieve a drop in output in the initial period of -7.5% under a Taylor rule (blue dashed line). The purple solid line reports the optimal policy under commitment (Ramsey plan). The vertical axes for \hat{Y} and π report deviations from steady state, in percentage points (annualised figures). The vertical axes for i and r^n report annualised percentage points.

interest rates and the natural rate of interest, under the assumption that the shock reverts to its steady state in periods $t = 10$, $t = 16$ and $t = 22$. It is only in the 16th contingency that the duration of the ELB under the OCP and FLFG coincides. If the natural rate reverts earlier (for example, in period $t = 10$), then FLFG implies that the ELB binds for longer than under the OCP, while if the natural rate stays low for longer (e.g., till period $t = 22$), then FLFG does not imply sufficient monetary stimulus since the central bank will raise rates as soon as the shock subsides.

We also contrast FLFG to the policy rules listed in Table 2. The optimal FLFG does worse than all other reaction functions, with the exception of the TTR. The reason is that this type of commitment does not adjust the duration of the policy accommodation in reaction to shocks.

4.7 Communicating State-Contingent Policy Rules

One major rationale for using a time-dependent policy commitment is that it is easy to communicate to the public. Communicating a state-contingent policy rule, however, need not be much more complex.

The Federal Reserve's formulation of a threshold strategy in December 2012 is an example of a state-contingent policy commitment that replaced a time-dependent policy. Under the new formulation, the Federal Reserve announced in its FOMC statement that it would

"keep the target range [...] at 0 to 1/4 percent and currently anticipates that this [...] will be appropriate at least as long as the unemployment rate remains above 6-1/2 percent, inflation between one and two years ahead is projected to be no more than half a percentage point above the Committee's 2 percent longer-run goal."

This type of commitment resembles much more closely the fully optimal state-contingent policy.

Consider the following communication strategy:

1. The central bank announces that it will keep the interest rate at zero until a particular quantitative threshold, or *target criterion*, is met for inflation and output, similar to its policy in 2012 (further specified below). This gives the market a way of forecasting the duration of the ELB by predicting the variables contained in the target criterion;
2. Once this threshold is met and the ELB is no longer binding, the interest rate is set freely to hit the prespecified target criterion.

As shown in EW2003, the optimal commitment is implemented in the two-equation model we have sketched if the quantitative threshold is specified using as a targeting criterion the index \tilde{P}_t , which is a weighted average of the price level and output as defined in equation (20). The threshold this index needs to reach for lift-off is denoted by \hat{P}_t^* , as specified in equation (21). Observe that the threshold in period $t + 1$ can be computed at time t . Thus, in each period the monetary authority can state what the threshold will be for a lift-off from the ELB going forward, based upon variables observed in period t .

As discussed in EW2003, a major advantage of this targeting rule is that its formulation is independent from the stochastic process for the natural rate of interest and the cost push shock. What is required of the policy-maker is to know the structural parameters of the model and values for output and the price level. The policy communication of the Federal Reserve in 2012 had this exact feature.

Our proposed make-up strategies HD-NGDPT and SDTR can be communicated along the same lines. The only difference is that the target criterion is now $\hat{\Gamma}_t = 0$, where this variable is defined in equation (26). For HD-NGDPT the criterion is $\hat{D}_t = 0$, where the targeting variables are defined in equation (27).

To be more specific, consider the HD-NGDPT and suppose a shock hits the economy at $t = 1$. In this period, even if the central bank cuts the interest rate to the ELB, it is unable to achieve its nominal GDP target; that is, $\hat{N}_1 = \hat{P}_1 + \hat{Y}_1 < 0$. At time $t = 1$, the central bank announces that the interest rate will remain at zero at least until nominal GDP reaches the threshold \hat{N}_2^* given by the following:

$$\hat{N}_2^* \equiv -\hat{\Gamma}_1 = -\hat{P}_1 - \hat{Y}_1 > 0 \quad (29)$$

which exactly compensates for the shortfall in the previous period. In other words, the central bank commits to making up for the drop in nominal GDP from period $t = 1$ by overshooting in period $t = 2$. Consider now the scenario in which the shock remains in the low state in period $t = 2$. The monetary authority then announces that the interest rate will remain at zero at least until nominal GDP reaches the following threshold:

$$\hat{N}_3^* \equiv -\hat{\Gamma}_2 = -\hat{P}_2 - \hat{Y}_2 + N_2^* > 0 \quad (30)$$

It thus compensates for its past two misses by overshooting in future periods. As in the case discussed in EW2003, the advantage of this type of targeting rule is that its implementation does not depend upon the stochastic nature of the underlying shock, but exclusively on observable variables. Moreover, the expected duration of the ELB can automatically be inferred by market participants, meaning the policy acts as an *automatic stabiliser*. Thus, for example, in the event of a new adverse demand shock, the market will infer that the threshold is further away from being satisfied. Consequently, it will adjust its expectations to reflect a longer duration at the ELB, which in turn will generate an additional monetary stimulus to counteract the shocks without the need for new announcements by the monetary authority. By contrast, in the case of a time-dependent commitment, the central bank would need to reformulate its policy each time in response to shocks, and the size of the adjustment would depend on the stochastic properties of the underlying disturbance.

4.8 *Odyssean and Delphic Forward Guidance*

Another illustration of the usefulness of accounting for uncertainty concerns the debate about the economic effects of central bank forward guidance. [Campbell et al. \(2012\)](#) distinguish between *Odyssean* and *Delphic* forward guidance: the former refers to the standard theory of forward guidance, in which the central bank makes announcements about future actions and is believed to be credible; the latter refers to the idea that forward guidance statements – for given economic fundamentals and monetary policy stance – may instead change agents' *beliefs* about future economic fundamentals.

In the case of Delphic forward guidance, a central bank announcement that is supposed to be expansionary – such as keeping rates lower for longer – may in fact have a contractionary effect if private-sector agents revise downwards their beliefs about economic fundamentals.

[Campbell et al. \(2012\)](#) can be placed in a broader literature on the effects of information in central-bank policy. Another recent paper in this literature is [Nakamura and Steinsson \(2018\)](#). The *information effect* in their analysis captures information about the state of the economy arising in response to surprise interest rate cuts or increases by the central bank. The underlying mechanism is the same: policy can affect private sector beliefs about economic fundamentals.

We conduct a small experiment that illustrates how we can coherently illustrate the effect of both types of forward guidance with the help of our toolkit. The main benefit of the toolkit here is that it provides a framework in which one can make a meaningful distinction between expected and realised duration of

the ELB episode. In a deterministic setup, the two concepts coincide. This is not the case with the toolkit, as we can change the expected duration at the ELB separately from the realised duration.

Consider the following deterministic process for the natural rate of interest. It turns negative in period $t = 1$ and returns to its steady state in period $t = 10$. Let us allow, however, for the possibility that while in actuality the shock will reverse in period $t = 10$, agents believe that there is a fixed probability (μ^b) in each period from $t = 2$ to $t = 9$ that the shock will revert to its steady state in the following period.

We consider two scenarios that lead the agents expected duration at the ELB to increase by one period: in the first, with Odyssean forward guidance, we impose the following rule:

$$i_t = \begin{cases} 0 & \text{for } t < \tau + 1 \\ \bar{r} + \phi_\pi \pi_t + \phi_y \hat{Y}_t & \text{otherwise} \end{cases} \quad (31)$$

The central bank announces it will keep the interest rate low for an additional period – that is one more quarter than prescribed under TTR. This is an expansionary policy.

In the second scenario, with Delphic forward guidance, we adjust the agents' beliefs about the reversal probability (μ^b) to obtain the same increase of one period of the expected duration of the ELB. In order to obtain a longer duration, μ^b has to increase. This entails a more contractionary shock than before. The two experiments are meant to separately study the effects of policy (Odyssean) and the effect of beliefs about fundamentals of the economy (Delphic).

Results are shown in Figure 7, in which the benchmark calibration is the same as before. The Odyssean forward guidance results in a increase in output, cutting the output contraction by almost half. Meanwhile, the Delphic forward guidance leads to a sharp output contraction.

This experiment highlights the critical role of beliefs in the model. It also illustrates that the toolkit allows for the possibility of shifting beliefs without a change in fundamentals, which remain fixed by the deterministic path of the natural rate of interest.

4.9 Robustness Checks

In the previous sections we explored the performance of our novel policy rules and found that they improve upon several alternatives documented in the literature, such as the PLT and NDGPT. We did so in an environment in which inflation on impact was slightly below its steady state under a Taylor rule (-0.5 percent). This resembles what the U.S. economy experienced during the Great Recession of 2008.

We repeat the experiment with different parameterisation of the natural rate and cost push shock in which deflation on impact under TTR is lower (0 percent) or higher (-2 percent). Our results are robust to both scenarios; that is, the HD-NGDPT and SDTR fare relatively well when compared with the PLT and NGDPT. In particular, the welfare loss under HD-NGDPT (SDTR) is approximately 1.6 (1.2) times as large as in the optimal commitment policy. In contrast, the welfare loss under both PLT and NGDPT is at least three times as large as in the OCP. In sections A.6.2 and A.6.3 in the appendix we report the detailed performance assessment of our candidate rules and provide plots for the impulse responses.

In the experiments so far, the inflation response has been weak due to the presence of a cost push shock, perfectly correlated with the drop in the natural interest rate. An alternative theory explaining why inflation was so stable in the Great Recession in the United States points to price rigidity. We explore this avenue by repeating the exercise with no cost push shock but with a degree of price rigidity such

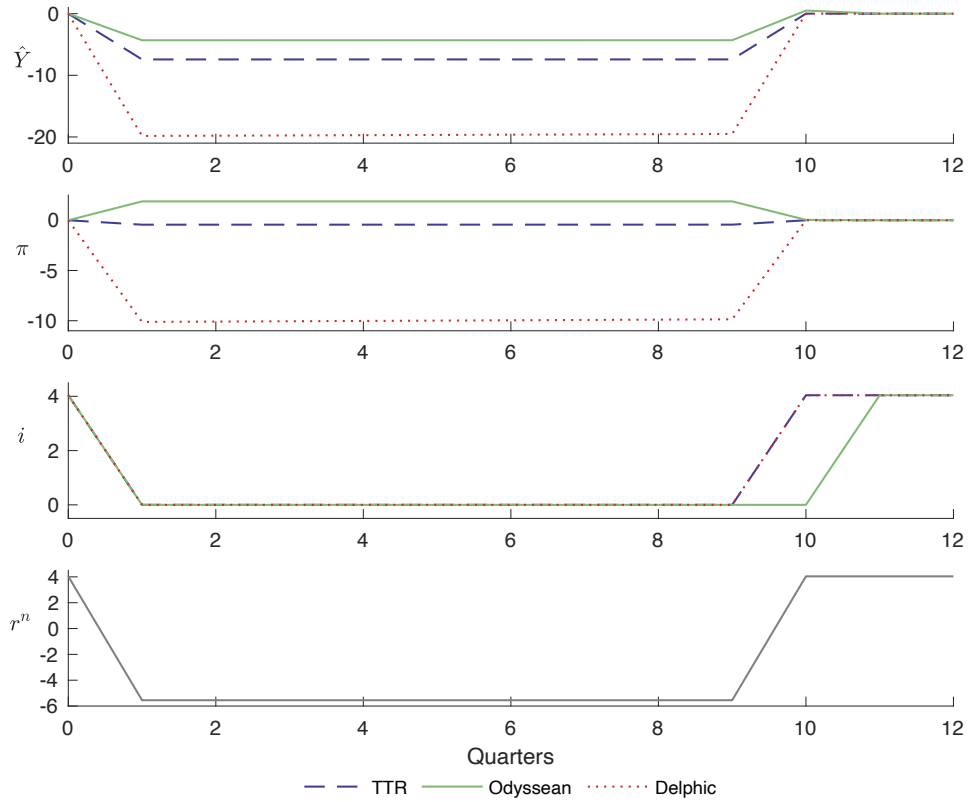

Figure 7: Odyssean vs. Delphic forward guidance (FG) experiment in simple two-equation NK model. Odyssean FG features commitment of central bank to one additional periods at ELB relative to Taylor rule (TTR). Delphic FG features lower transition probability of shock, $1 - \mu^b$. Both scenarios have expected duration at ELB of 10 quarters, TTR has expected duration at ELB of 9 quarters. Lines represent contingency 10 for output (\hat{Y}), inflation (π), the nominal interest rate (i) and the natural rate (r^n). Calibration is the same as in section 4.3, achieving a drop in output in the initial period of -7.5% and a fall in inflation to -0.5% under discretion in response to a natural rate shock and a perfectly correlated cost push shock (TTR, blue solid line). Transition probability under Delphic FG is $\mu^b = 0.09091$. The vertical axes for \hat{Y} and π report deviations from steady state, in percentage points (annualised figures). The vertical axis for i and r^n report annualised percentage points.

that, under the TTR, inflation again drops to -0.5 percent on impact. We refer the reader to the appendix (section A.6.4) for welfare analysis and dynamic responses. Our two rules remain very good compared to the optimal policy commitment. On the other hand, strategies that were comparable to ours, the ATR and SUP, now tend to fare significantly worse than OCP.

In the last robustness check we perform, we choose the policy parameters to maximise welfare according to equation (25).³⁰ The results are reported in Table A.8 in the appendix (section A.6.5) while the optimal parameters are listed in Table A.2. In this setting, only ATR and SUP – rules that display welfare losses comparable to ours – improve slightly in terms of welfare. All other optimised policies are virtually unchanged.

5 Medium-Scale DSGE Model

The results discussed so far were derived using a simple two-equation NK model. In this section we show that the findings generalise to a medium-scale DSGE model and are not an artefact of the simple structure of the baseline exercise. Rules that imply substantial *make-up* behaviour or feature inertia in the path of interest rates have the best outcome. Our two proposed policies, HD-NGDPT and SDTR, outperform all alternative candidates by implying substantial stimulus compared to a simple Taylor rule. As before, a price level target and nominal GDP target do not perform as well in an environment with relatively stable prices. This section also serves to illustrate how our toolkit can easily handle medium-scale models.

For this exercise, we implement the FRBNY DSGE as outlined in [Del Negro, Giannoni and Patterson \(2013\)](#). We consider the model as a reasonable description of the U.S. economy and simulate the Great Recession with it. In all our figures, we plot the data against our simulations. Figure 8 shows the pre-crisis trend and the actual path for the U.S. nominal GDP and price level. We calibrate the model to match a similar decline of both variables as observed in the data. For the calibration, we use the policy rule proposed and estimated in [Del Negro, Giannoni and Patterson \(2013\)](#) as the one prevailing in the data-generating process (equation A.6).³¹ This gives us the ideal testing grounds for the reaction functions introduced in the previous section.³²

As an illustration, we assume that the shock that gave rise to the Great Recession reverted to steady state around the time the Federal Reserve started increasing interest rates in 2015, though this is clearly an exaggeration. We contemplate this scenario because it makes the thought experiment straightforward to interpret and comparable to our previous simulations.

Figure 9 compares the FRBNY policy rule with the four targeting rules and the data. We see that PLT and NGDPT do not improve significantly upon the FRBNY rule, which is consistent with our experiment in the simple model. The reason, as before, is that the small drop in the price level does not generate strong enough of a commitment to low future rates. The FRBNY rule implies 28 quarters at the ELB, as observed in the data. Relative to this, PLT and NGDPT only command five additional quarters at the lower bound after the shock reverts to the steady state. This is in stark contrast to our newly proposed rules: HD-NGDPT (SDTR) implies 16 (15) additional quarters at the ELB relative to the baseline, postponing the lift-off from zero well into 2019. This aggressive policy improves outcomes considerably: while output drops to -8.5 percent under the FRBNY rule and to -6.3 percent (-6.0 percent) under PLT (NGDPT), the

³⁰Targeting rules are not re-parameterised.

³¹In a medium-scale model featuring many state variables, such as the FRBNY DSGE model, optimal commitment is cumbersome to derive. We therefore take the FRBNY policy as our baseline.

³²Section A.4 in the Appendix contains details on the model and its calibration.

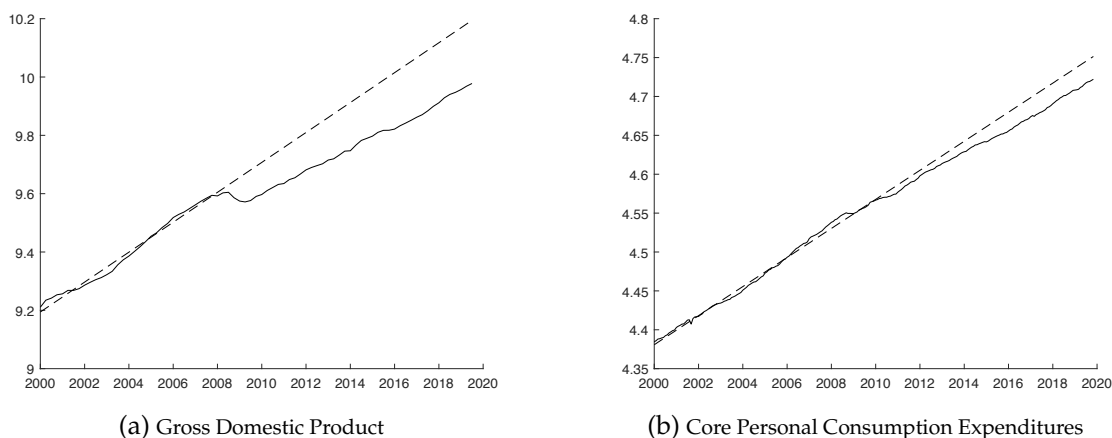

Figure 8: U.S. Gross Domestic Product (in Billions of Dollars) and Personal Consumption Expenditures ex. Food and Energy (Chain-Type Price Index, 2012=100). All series are in log-points and seasonally adjusted. The dashed line represents a linear trend estimated in the pre-Great Recession period (2000-Q1 to 2007-Q2). Data from the U.S. Bureau of Economic Analysis. For details on the data source see footnote 35.

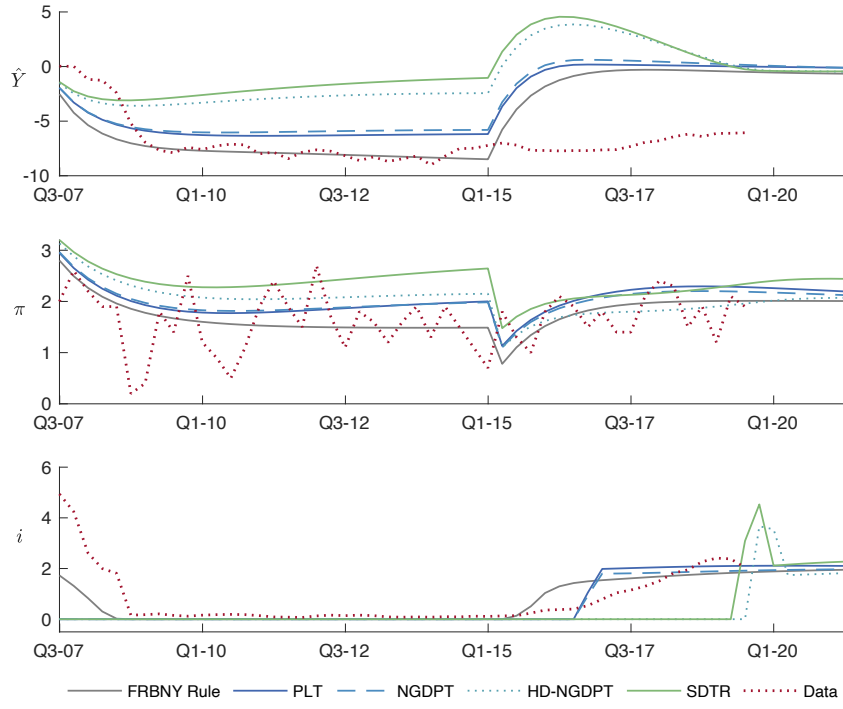

maximum drop in output under HD-NGDPT (SDTR) is -3.6 percent (-3.1 percent). In addition, output reaches its trough early and recovers thereafter. This improvement is achieved at the expense of a modest overshooting of inflation relative to the other rules.

We can assess the costs in term of output loss associated with the Federal Reserve’s inability to flatten the path of the expected Federal Funds Rate in the early stages of the U.S. Great Recession. To this end, we compare the realised output loss implied by the model to trend output. For the period 2007-Q3 to 2020-Q1, the FRBNY Rule implies an average annualised output gap of -5.07 percent (column (8) in Table 3). Our proposed rules reduce this number considerably: -0.34 percent for SDTR and -1.01 percent for HD-NGDPT. This means that the cumulative output gap since the Great Recession would have been almost closed by the first quarter of 2020 had the Federal Reserve implemented the SDTR policy rule. We also report the model-implied price level in 2020-Q1 (see column (9) of Table 3). Under the FRBNY rule, the price level is still 3.5 percent below trend in 2020-Q1, while HD-NGDPT closes the price level gap (0.4 percent above target) and SDTR overcompensates (4.2 percent above target). While PLT closes the price level gap by 2020-Q1, it does not provide enough stimulus, and it implies a rather large average annualised output gap of -3.74 percent.

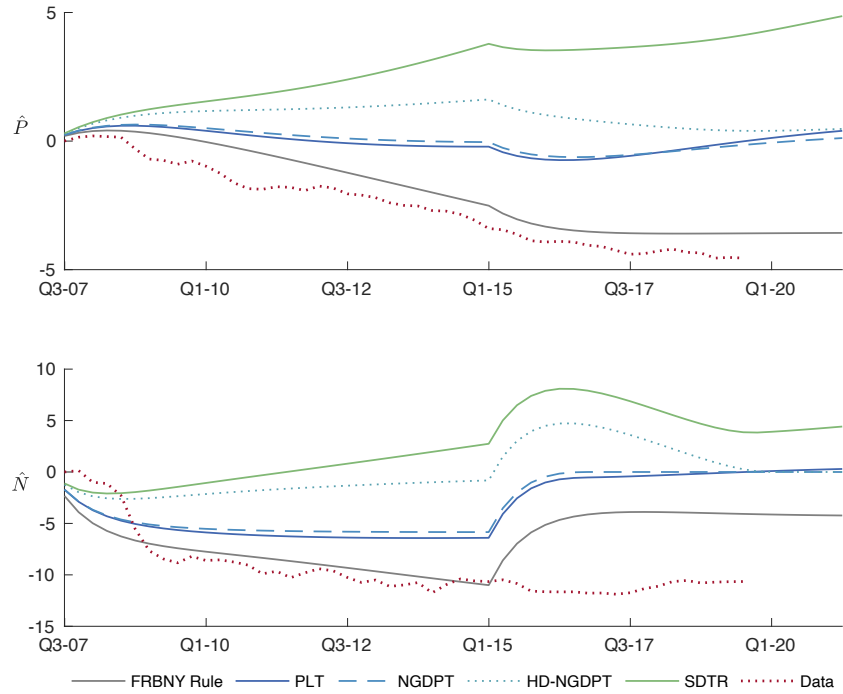

Notably, we calibrate our model such that we exactly hit the relatively short expected duration of the ELB binding for four quarters at the early stages of the Great Recession, as found in surveys of professional forecasters. This is one benefit of the stochastic structure of the toolkit: we can simultaneously target moments of output loss and expectations about the duration of the ELB episode.

Our analysis suggests that had the Federal Reserve been able to credibly announce and implement HD-NGDPT or SDTR, the path of the Federal Funds Rate expected by market participants would have been considerably flatter (compare to Figure A.20a in the appendix). The expected duration at the ELB would have been about three times higher (12.9 and 13.4 quarters for HD-NGDPT and SDTR, respectively).³³ This change is solely due to a difference in policy, as the fundamental shock to the economy is held constant.

³³These numbers are different from the ones reported in column 2 in Table 3 because in this section we condition on having reached the ELB. This makes the numbers comparable to the survey forecast of four quarters at the ELB. In Table 3 we report the unconditional expectation, i.e. from the time when the shock hits. The two metrics can differ because of the presence of regime 0.

(a) Paths for output (\hat{Y}), inflation (π) and nominal interest rate (i)

(b) Paths for price level (\hat{P}), nominal output (\hat{N})

Figure 9: Dynamic response to a preference shock and a correlated cost push shock in FRBNY model, under different policy rules. Dotted red line is data. The two-state Markov shocks switch to low state in Q4-07 and revert to the absorbing state after 32 quarters (32nd contingency). The vertical axes for \hat{Y} and \hat{N} report deviations from detrended steady state, in percentage points (annualised figures). The vertical axes for π and the i report annualised percentage points. The vertical axis for \hat{P} reports percent deviations from its trend. The horizontal axis shows quarter and calendar year. See section A.2 for details on data and section A.4.2 for calibration. The list of acronyms is detailed in Table 1.

Table 3, Figures 10 and A.17 show the results for the full set of reaction functions.³⁴ Comparing the welfare loss across rules, we see that HD-NGDPT and SDTR outperform all others. Our proposals generate a loss that is only one-third of the one under the FRBNY rule since they imply substantial additional stimulus. Indeed, the expected duration at the ELB (column 2 in Table 3) is much longer than in any alternative proposal. Of the remaining policies, ATR and SUP again perform well and come the closest to our two candidate rules. Appendix A.5.2 discusses the case in which the ELB constraint is not imposed. Our two proposed rules are again among the best performing ones.

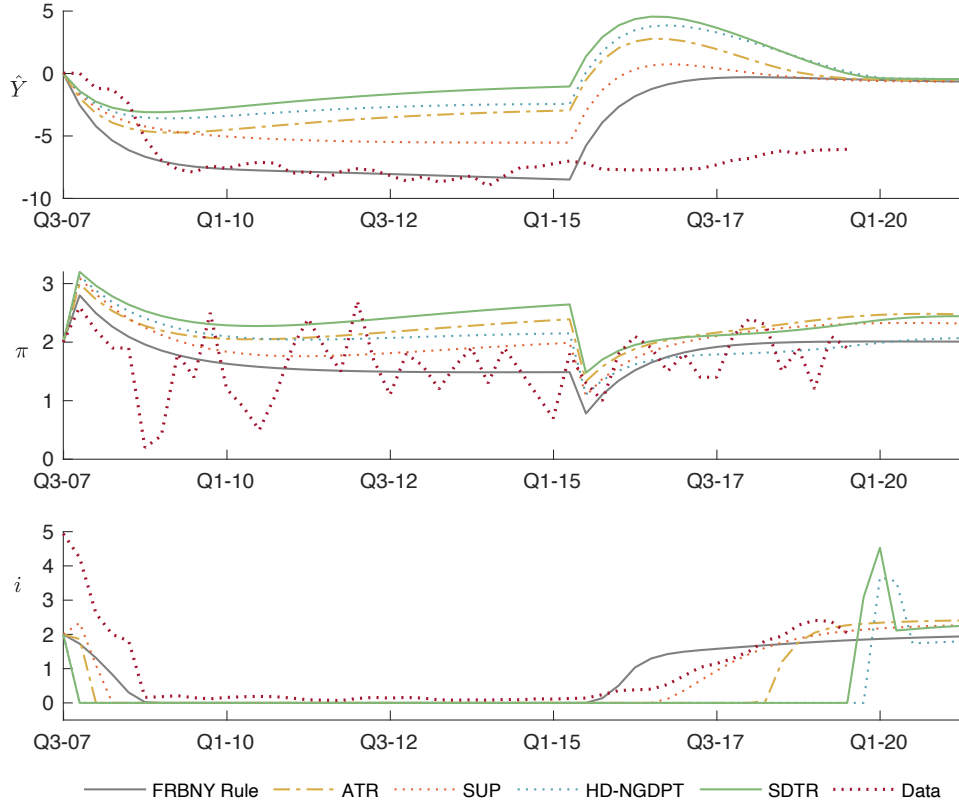

Figure 10: Dynamic response to a preference shock and a correlated cost push shock in FRBNY model, under baseline policy rules. Lines show paths for output (\hat{Y}_t), inflation (π), the nominal interest rate (i), and nominal GDP (\hat{N}). Dotted red line is data. The two-state Markov shocks switch to low state in Q4-07 and revert to the absorbing state after 32 quarters (32nd contingency). The vertical axes for \hat{Y}_t and \hat{N} report deviations from detrended steady state, in percentage points (annualised figures). The vertical axes for π and the i report annualised percentage points. The horizontal axis shows quarter and calendar year. See section A.2 for details on data and section A.4.2 for calibration. The list of acronyms is detailed in Table 1. FRBNY Rule refers to equation (A.6).

³⁴Appendix A.6.6 shows impulse response functions and additional variables for all rules.

Table 3: Some metrics for interest rate rules in the FRBNY model in the presence of a preference shock and correlated cost push shock. All rows except the first show values normalised with respect to the modified Taylor rule in [Del Negro, Giannomi and Patterson \(2013\)](#) (FRBNY Rule, first row). Column (1) reports the welfare loss computed from a quadratic loss function for the central bank with equal weights and an inflation target, see equation (A.7); Column (2) displays the unconditional expected duration of the Effective Lower Bound (regimes 1 and 2); Columns (3)-(5) report a summary measure of deviations of the endogenous variables from target, computed according to equation A.5; Columns (6) and (7) show the response on impact, in annual percentage points, of the output gap and inflation to a preference shock and a correlated cost push shock such that output falls by 8.5% and inflation by 0.5% under FRBNY Rule; Columns (8) shows average annualised absolute deviations of the output gap from steady state, for contingency 32; Finally, Column (9) reports the relative deviation of the price level from trend in 2020-Q1, for contingency 32. Figures in Columns (8) and (9) are not normalised with respect to the FRBNY Rule. See section A.4.2 for details on calibration and specification of FLFG rule. The list of acronyms is detailed in Table 1.

6 Conclusions

We provide a toolkit to solve DSGE models that involve occasionally binding constraints. The solution method generalises that of Eggertsson and Woodford (2003) and exploits the properties of a two-state Markov process for the exogenous disturbances. The toolkit performs well even in the presence of a large number of state variables and features a tractable stochastic structure. This modelling assumption is particularly relevant in analysing macroeconomic problems in which uncertainty is important, as in the case of forward guidance.

We used the toolkit to study the performance of policy rules in economies facing the ELB. Our two newly proposed strategies, a *history-dependent nominal GDP target* and a *symmetric dual-objective target*, consistently outperform most rules documented in the literature, especially reaction functions based on price-level or nominal-GDP targeting. We showed that the latter two rules provide insufficient stimulus during economic downturns characterised by a small drop in the price level, as experienced in the U.S. Great Recession episode. In addition, our rules are easy to communicate to the public in the form of a *state-contingent* strategy and are robust to different crisis scenarios.

Finally, we evaluated the proposed rules' performance in a medium-scale DSGE model of the U.S. economy. Our analysis suggests that our *make-up* strategies – if credibly conveyed to market participants by the Federal Reserve – would have resulted in a much longer expected duration at the ELB after the Great Recession, and in an 80-percent reduction in lost output. Similarly, the Fed's monetary policy strategy outlined in the recently revised *Consensus Statement* (Powell 2020) would have reduced the output contraction by more than a quarter.
